Abstract: Long-distance dispersal is one of the main drivers structuring the distribution of marine biodiversity. This study reports the first occurrence of *Macrocystis pyrifera* and *Durvillaea antarctica* rafts on the southwestern warm temperate coast of the Atlantic Ocean. Our results indicate that an extreme meteo-oceanographic event, characterized by a northward displacement of cold sub-Antarctic oceanic waters driven by an extratropical cyclone, could account for these unusual occurrences. A niche model based on known current distribution and maximum entropy principle (MAXENT), revealed the availability of suitable habitats at lower latitudes, outside their actual distribution edges. The distributional boundaries, mainly driven by temperature and irradiance, suggest the existence of environmental suitability in warm temperate areas, as well as in the Northern Hemisphere off Atlantic and Asian coasts. These theoretical edges and respective environmental drivers agree with the physiological affinities of both species, supporting the hypothesis that these variables act as limiting factors for their occurrences in tropical or warmer areas. Emerging regions can function as...
refuges and stepping-stones, providing substrate with adequate habitat conditions for recruitment of propagules, allowing eventual colonization. Long dispersal events reinforce the need for an extensive discussion on selective management of natural dispersion, biological invasions, refuge mapping and conservation initiatives in a transnational perspective.

**Keywords:** Kelp rafts; marine migration; niche model; biogeography; upwelling; extratropical cyclone

### 1. Introduction

The dispersal of marine organisms is one of the main ecological and evolutionary drivers of marine biodiversity composition and structure, with currents representing one of the principal players in these processes [1–3]. Currents can influence the range of dispersal of migrant populations, promote connectivity, and assist in the process of finding suitable habitats [4–7]. Besides providing transport, currents also play a role in determining niche characteristics, limiting physiological and developmental processes, that require specific abiotic conditions such as temperatures, salinity, and nutrient concentrations [8,9]. Such aspects have been receiving more attention in recent years due to climate change. Global warming is producing critical changes in ocean circulation patterns, niche availability and characteristics, and biodiversity redistribution [10,11]. At the same time, changes in global ocean circulation patterns can interact locally with specific regional climatic conditions. In the South Atlantic more frequent and intense storms have been observed in recent decades, which compromise oceanic circulation and migration processes [12–14]. Currents acting together with storm-winds are efficient dispersal mechanisms for floating strategists and associated communities. One such community affected by storms is kelp forests [1,15].

During storms, kelps get detached from the substrate. Many of the detached plants become entangled in other detached kelp plants and eventually form what are called kelp rafts [16]. These floating masses, sometimes abundant and with a diversified fauna and flora, can be transported rapidly and beyond their distributional boundaries [1,15,16]. Oceanographic/climatic events can work together to transport an entire specimen, or kelp rafts, with potentially viable propagules, to suitable far-off niches. However, effective species establishment will depend on a combination of abiotic and biotic conditions, which will be influenced by the settlement of the juveniles and the development of the propagules [17–19].

Density dependent mechanisms, such as competition, predation, and herbivory, represent additional dispersal and developmental barriers in marine environments [1,20,21]. However, specific benthic organisms or community structure can change micro niche conditions, facilitating settlement and development of invertebrates and primary producers [22,23].

The combination of all these physico-chemical and biological processes will produce the realized niche, which can be recognized as the space currently occupied by a species, after the migratory and selective pressures imposed by positive and negative biological interactions. This is distinct from the fundamental niche [8,19,24–27], where the range of environmental conditions within which a species has a suitable habitat (i.e., can in theory survive and persist), but might not occur there due to biological interactions or processes such as competitive exclusion or limited migration. These concepts were refined by Hutchinson (1957), who hypothesized that the fundamental niche could be mapped in physical space, thus predicting where species should be able to live. The effectiveness of niche modeling tools provides support to Hutchinson’s assumptions [28,29]. Nowadays, species distribution models are recognized as an important tool to determine niche suitability for marine organisms, particularly macroalgae, in contemporary climatic and oceanographic spaces [30–33].

Macroalgae play a key role in different marine environments, sometimes building biogenic reefs or underwater forests. These organisms influence and create niches, which represent, food, shelter and substrate for a high diversity of marine organisms, especially in temperate environments [34,35].
Kelp forest ecosystems are among the largest biogenic structures found in the benthic marine system [36]. Primary producers were recognized even by ancient naturalists like Charles Darwin, who emphasized the fundamental ecological importance of these subtidal forests in high latitudes of South America [37]. These environments are considered common and abundant in temperate and sub-Antarctic regions [38,39].

One of the dominant species of kelp forests is *Macrocystis pyrifera* (Linnaeus) C. Agardh, commonly known as giant kelp. It occurs in both the Northern Hemisphere (western coast of North America) and the Southern Hemisphere (i.e., Australia, New Zealand, South Africa, sub-Antarctic islands, and the western and eastern coasts of South America) [31]. In the Southern Atlantic, along the east coast of South America, its northernmost boundary is the northern region of Argentinean Patagonia, Craker Bay (42°56′ S 64°27′ W) [40,41]. Molecular and fossil characterization indicates that this taxon originates in the North American Pacific Coast, migrating to the Southern Hemisphere 10,000 years ago, during a colder period. Similar North to South migrations have been hypothesized in the Atlantic Ocean [42]. The ancestor of both *Laminaria abyssalis* A.B. Joly & E.C. Oliveira and *L. pallida* Greville, originated in the Northern Hemisphere and migrated south during cold periods.

Kelps have a biphasic life cycle. Ladah & Zertuche-Gonzales (2007) showed that *Macrocystis* can survive long periods in its microscopic forms (gametophytes), which would enable it to survive under warmer conditions in a seed bank analogue turf environment. Interestingly, it has been suggested that vegetative propagation of these undifferentiated filamentous haploid forms can have contributed to antitropical east Pacific distribution [43]. Once the conditions become favorable, the gametophytes would continue its life cycle to form the macroscopic thallus (sporophytes) [44]. The sporophytes of *Macrocystis pyrifera* can grow up to 30 m in length, on a hard substrate, while it is kept erect in the water column by aerenchyma or floater vesicles, which also facilitate dispersal [45,46]. They form large floating patches or “rafts” that can travel long distances for a long period of time (i.e., over three months), with their reproductive capacity still viable [45].

The distribution of *Durvillaea antarctica* (Chamisso) Hariot is limited to the Southern Hemisphere [31,47]. It has a diplontic life cycle. Despite the absence of an alternate phase in the life cycle, this species can remain afloat for more than one month (because of the presence of aerenchyma) in cool water and low irradiance, typical conditions for winter and part of spring or fall. Temperatures of up to 17 °C, combined with higher irradiance during summer (maximal values 16.1–21.8 W m⁻²) were correlated with significant biomass losses and rapid destruction of *Durvillaea* rafts [44]. However, some kelp populations have colonized habitats with higher temperatures and irradiances, at lower latitudes, such as those that were observed at the western shores of southern California to Mexico, northern Chile to Peru, south-western South Africa and western Australia [48]. In such cases, despite the relatively lower latitude, environments are influenced by nutrient-rich upwelled waters or cold eastern boundary currents that flow towards the Equator [35,48]. The few kelp species that occur in tropical environments have their distributions restricted to deeper zones within the photic zone, where light and nutrients are sufficient for their growth [31]. *Laminaria abyssalis*, an endemic to the Brazilian coast, is an example of a tropical kelp. This species occurs at depths of between 40–115 m, and uses rhodolith beds as a substrate [49].

Tropical kelp forests are considered relict species from an immigration of shallow water populations. During the Pleistocene some populations expanded their distributional boundaries to lower latitudes due to the lower Atlantic temperatures, that in these equatorial regions were up to 5 °C below the mean values observed in the surface during the last decade [50,51]. Presently, climatic projections suggest potential changes in species distribution [52], especially for subtidal kelps, which are vulnerable to sea surface temperature (SST) changes, due to their affinities with cold water [51]. Losses of kelp forests’ distributional ranges are reported in various regions of the world [33,53,54]. The reduction of *Saccorhiza polyschides* (Lightfoot) Batters and *Laminaria hyperborea* (Gunnerus) Foslie populations on the northern coast of Spain was related to the increase in SST and the reduction of upwelling intensity in the region [54]. However, regional cooling has been observed
in coastal areas of South America [55] and South Africa [56]. In South Africa, this resulted in the extension of the known distribution limits of Ecklonia maxima (Osbeck) Papenfuss. Some studies suggest that kelp may find refuge in deeper environments, far from the general warming tendency of oceanic surface waters [31,33]. Thus, the existence of temperate algae refuges, even in tropical or warm temperate environments, is of extreme relevance, not only for understanding biogeographic patterns, but for conservation purposes also. Graham et al. (2007) modeled deep-water kelp refugia, and with the use of the model’s predictions they have discovered dense and extensive populations of Eisenia galapagensis in deep waters of the Galapagos archipelago. Although modeling constitutes an essential tool for the discussion of marine macroecological processes [57], there are no published articles with models predicting niche habitat suitability for M. pyrifera and D. antarctica, two of the most important kelp species.

Therefore, better understandings of ecological and evolutionary mechanisms would contribute to the comprehension of key population dynamic and resilience. The definition of target foundation species or groups and mapping niche suitability may improve management, when considering future needs for biodiversity management or conservation [58,59]. Differentiating natural drift-refuge colonization process from anthropogenic transport-bioinvasion process is a crucial task [60]. This aspect reinforces discussion about large scale dispersal in an eco-evolutionary framework [61] and should influence stakeholder decision regarding the necessity of conservationist intervention or complete eradication of a migrant target population [60,61].

Here we report (1) the first observation of rafts of two kelp species (M. pyrifera and D. Antarctica) on the Brazilian and Uruguayan coasts; (2) provides the general physiological state of immigrant specimens; (3) discusses the possible origin of these rafts; (4) and model both species habitat suitability considering dispersion routs, potential settlement and colonization on a global scale. Moreover, we characterize the oceanographic processes that caused this dispersal event and discuss implications of these dispersal events considering coastal management and conservation.

2. Materials and Methods

2.1. Study Area

The kelp rafts were found along the beach of Campeche in Florianópolis (27°39’23.21” S; 48°28’13.13” W), Santa Catarina State, southern Brazil, and the beaches of La Paloma, Punta del Diablo, Santa Teresa, La Coronilla and Barra del Chuy, Uruguay (between 33°38’58.58” S; 53°27’58.03” W and 34°39’52.5” S; 54°10’0” W). The continental shelf off this region is located near the Brazil-Malvinas Confluence (BMC) region, located at 38°±2” [59,62]. The Falkland Current (Malvinas Current) acts as a branch of the sub-Antarctic Front, which is the northernmost oceanographic process associated with the Antarctic Circumpolar Current in the Drake Passage [63]. These cold, sub-Antarctic water masses flow from the south northwards and meet the warmer and more saline waters from the Brazil Current, between latitudes 36° and 39° S giving rise to the Subtropical Convergence [64]. This is also where the South Atlantic Central Water (SACW) current is formed (Figure 1). The nutrient rich, low temperature current intrudes the shallower strata near the continental shelf and is responsible for the common upwelling phenomena, over a 27 km section of the coast [65], from the southern region of Santa Catarina Island (27°35’ S) to the Cape Santa Marta (28°37' S) [62,66]. During austral winters, this area is influenced by the La Plata river plume, which increases nutrients, and the Sub-Antarctic currents, which reduce the temperatures [67,68].

The southwestern Atlantic biogeographic eccline described above is also known as the “Arc of Capricorn”, representing the southernmost limit of distribution of many tropical organisms [62,69], a warm temperate biogeographic province [70] or general perspective [71]. This region presents a clear seasonal pattern with lowest surface temperatures around 16 °C observed during winter, and the highest temperatures up to 28 °C observed during summer [62,72]. However, a more stable colder
condition is observed in its deeper areas as a consequence of the more frequent influence of the SACW [73].

Figure 1. Sampling sites (black points) and main marine currents observed in the drifting region.

2.2. Collection and Characterization

The rafted kelp individuals of Macrocystis pyrifera and Durvillaea antarctica were collected on the Uruguayan site between 22 July and 3 August and on the Brazilian site between 26 and 29 September 2016, washed-up on the sand strip and drifting in the region of burst. All the individuals were collected and stored in thermal boxes for transport to the Laboratory of Phycology (Federal University of Santa Catarina, Florianópolis, Santa Catarina, Brazil); due to the massive wash-ups on the Uruguayan coast, only some specimens were collected for transport to the Centro Universitario Regional del Este (CURE, UdelaR, Rocha, Uruguay).

To analyze the physiological conditions, of the washed-up specimens, optimum quantum yield was evaluated in three random benthic Macrocystis specimens. These specimens were from Punta Arenas, Chile (from different periods, to represent periods of before and after the dispersion event), and they were compared to washed-up plants that were collected in Brazil. Thalli were dark acclimated for 15 min using leaf clips (Diving-LC, Walz) that were placed ~10 cm from the base of each blade, following procedures applied by Edwards and Kim (2010) with North American populations. Maximum (Fm) and the minimum (Fo) fluorescence, and the PSII optimum quantum yield (Fv/Fm) were determined for all three specimens. Relative electron transport rates (rETRs) were calculated as rETR = Φ PSII × PPFD; where Φ PSII is the quantum efficiency of PSII and PPFD is the photosynthetic photon flux density of photosynthetically active radiation (PAR). Rapid light curves (RLCs) were generated using Walz pre-installed routine. Evaluation of α, Ek and rETRmax, (where α = photosynthetic efficiency under non-saturating irradiances, Ek = saturation irradiance, and rETRmax = the relative maximum rate of electron transfer to photosystem II under saturation irradiances) was accomplished using Platt et al. (1980) equation. RLCs were not evaluated in the Chilean populations.

Samples of M. pyrifera were identified based on its external morphology [38], while for D. antarctica transverse sections were cut to identify it anatomically [74] (Appendix A). To evaluate the presence of reproductive structures, all morphoanatomical characters, as described by [75], were considered. Fragments from each individual were collected, cleaned and stored in silica gel, for future molecular analyses. Specimens were deposited at the Herbarium FLOR, Federal University of Santa Catarina, Brazil (FLOR 63005, FLOR 63006, FLOR 63007, FLOR 63008, FLOR 63009 and FLOR 630010).
2.3. Niche Modeling Procedures

Macroecological niches of *M. pyrifera* and *D. antarctica* were modeled globally using MaxEnt, a robust method, to predict species distributions with presence-only data [76]. This uses the principle of maximum entropy [77], that compares the occurrence records with pseudo-absences generated from background locations, i.e., possible occurrence areas where the presence/absence of species is unknown [78]. The algorithm used in the program was extensively tested in several previous studies [27,77,79] and proved to be a reliable tool to be applied in this context. This method provides a suitable technique, as only data collected from the literature is applied to feed the model [57].

2.4. Environmental Variables and Occurrence Data

The environmental variables used to generate niche models were downloaded from Bio-Oracle [29] for the global ocean, under the Behrmann equal-area projection. The selection of variables considered the biology and ecology of kelp forest species (e.g., [80,81]), as well as their degree of collinearity inferred with Variance Inflation Factor (VIF) [82]. Environmental variables with VIF scores above 10 were not considered for modelling purposes [82]. This procedure resulted in 9 variables used as input for models.

Georeferenced occurrence data for the whole distribution of species were compiled from the Australian Virtual Database, Global Biodiversity Information Facility (GBIF, www.gbif.org, accessed on 10 December 2016), and scientific journal articles (Table A1). These data were gridded to the spatial resolution of environmental data, and surplus overlapped entries were discarded to eliminate replication. To further reduce the effect of spatial autocorrelation in the models (see [83]), the correlation of environmental variables within the range of occurrence records was determined as a function of geographic distance with Mantel tests under $1 \times 10^4$ permutations (e.g., [83]). The records were trimmed by randomly selecting one record only, within the radius of the minimum non-significant ($\alpha = 0.05$) spatially correlated distance. This resulted in 224 records for *M. pyrifera* and 112 for *D. antarctica* as input for the models (from a total of 889 records originally compiled for *M. pyrifera* and 616 for *D. Antarctica*) (Table S1).

To reduce estimation bias introduced by the likely unbalanced distribution of data, background information (i.e., “pseudo-absences”) were randomly selected per species from a kernel density estimation surface developed with the occurrence records and a spatial grid conformal in resolution with the environmental data (e.g., [81,84,85]). This procedure also restricted the extent of models to the actual distribution of species, a crucial step while modelling ecological niches [81,86].

Over-fitting was controlled by tuning the optimal parameters of models from a range of MaxEnt regularization multipliers (from 0.5 to 5; 0.5 step) and feature classes (i.e., linear, quadratic, hinge, product and threshold) (see [87] for details). A cross-validation framework was implemented in this process to evaluate the performance of models. Statistically independent datasets were produced by partitioning the occurrence records (both presences and pseudo-absences) into 10 distinct latitudinal bands [88]. Models testing different parameters interactively fitted data with one band withheld at a time, where performance was evaluated with the area under the curve (AUC) [57,89] and sensitivity (true positive rate; [89]). Final maps were developed with the combination of parameters retrieving higher average AUC values (identified in cross-validation). These were reclassified to represent suitable/unsuitable areas with the minimum training presence threshold [87,90]. All niche modelling analyses were performed with R (R Development Core Team, 2017) using the packages dismo, ecospat, parallel, raster and SDMTool.

2.5. Oceanographic Characterization before and during Dispersion Event

The Southwest Atlantic surface temperature data, before and during the dispersion event, were obtained from the NOAA database. To evaluate the influence of a specific extreme climate episode on the flux of cold water masses from the South Atlantic towards North,
we verified the sea surface temperature (SST) from 1 January to 10 October 2016. To exclude the possibility of annual recurrence of the phenomenon, we also verified the flux of water masses during the same period for 2013, 2014 and 2015. SST-anoalyses between 2013 and 2016 were evaluated (https://coralreefwatch.noaa.gov/satellite/bleaching5km/index.php). The Group for High-Resolution Sea Surface Temperature (GHRSST) global Level 4 data was obtained from the Physical Oceanography Distributed Active Archive Center (PODAAC), at the NOAA National Centers for Environmental Information, by the satellite AVHRR-ONLY (AVHRR-OI).

3. Results

Entire plants of *M. pyrifera* and *D. antarctica* were collected at La Paloma, Punta del Diablo, Santa Teresa, La Coronilla and Barra del Chuy, east of Uruguay, on 3 August and successive days. A total of 4 m$^3$ of *M. pyrifera* and 1.3 m$^3$ of *D. antarctica* were collected from a 2.3 km stretch of beach at Corumbá beach in La Paloma. During the following month, fragments of both species were collected on Campeche beach, along the eastern portion of Santa Catarina Island, southern Brazil. Algae reached Campeche beach on four consecutive days. We collected a total of 1158 g of *M. pyrifera* and 3083 g of *D. antarctica*, their largest recorded sizes were 180 cm and 151 cm, respectively (Figure A1). The *M. pyrifera* rafts that washed-up in Brazil had similar optimum quantum yield variability as compared to plants from natural populations from Chile and North America (Table 1). Reproductive structures were only present in *M. pyrifera* plants from the Uruguayan rafts but absent in both species from the Brazilian rafts.

Figure 2 shows four sea surface temperature (SST) maps, one per year, and an intrusion of colder waters flowing along the Patagonia shelf, following the Malvinas current (MC) towards the southern coast of Brazil. The lower temperatures recorded were approximately 15 °C in 2013, 2014 and 2015. However, for the same period in 2016, these water masses were colder than compared to 2013, 2014 and 2015, and reached lower latitudes closer to the coast. Figure 2 characterizes a strong advection of cold waters (8–12 °C) from the MC along the Uruguayan and Brazilian shelves. The SST-Anomaly evaluation corroborates previous analyses in the sense that they show a significant inter-annual variability of this cold intrusion.

The SST anomaly, with respect to the long term mean, is presented in Figure 3. In the four maps, warm colors are predominant and this is an indication of the warming of the surface waters of the region. The thermal anomaly along the southernmost third of the South American continental shelf reached 4 °C in 2016. The cold incursion reaches as far north as the southern tip of the South Brazil Bight (SC, Brazil). Animation of daily maps similar to those in Figure 2 clearly shows the northward evolution of the plume. The continuity of the cold anomaly along the coast shown in Figure 3 for 2016-09 suggests northward advection of MC waters- and its contents.
The predicted niche suitability in the Southwestern Atlantic Ocean was broader than the known distribution for both species, where the nearest known occurrence distant hundreds of kilometers. Bottom light also showed to be important restricting vertical distributions, and for *M. pyrifera*, ice thickness (Figure 5).

### Niche Models at the Global Scale

The niche models developed for *M. pyrifera* and *D. antarctica* presented a near-perfect prediction, with mean AUC and mean sensitivity scores inferred in cross-validation >0.9 and >0.95, respectively. The predicted niche suitability in the Southwestern Atlantic Ocean was broader than the known distribution for both species, where the nearest known occurrence distant hundreds of kilometers from the predicted range margin (Figure 4). Among the environmental predictors analyzed, primary productivity (PP), temperatures and phosphates presented the highest contribution to the performance of model for both species. Bottom light also showed to be important restricting vertical distributions, and for *M. pyrifera*, ice thickness (Figure 5).
Involving passive dispersion of these species recorded distances of tens of kilometers [46,96]. Our data due to morphological structures, such as aerocysts, which provide buoyancy [39,45,94,95]. Studies range, as was hypothesized by Tala et al. [87] and reinforced here by our modeling evaluation.

Suitable temperature, irradiance and a source for colonization of the mapped suitable niches. The niche suitability, which was detected in Brazil [93]. Mature sporophylls from the *M. pyrifera* area, during this period [92]. Despite a long drift process, the oceanographic and climatic conditions coasts showed that they have the physiological tools to acclimatize to the floating conditions in this species, is the Falkland Islands [91]. The washed up plants, observed on the Uruguayan and Brazilian experts around the world (B.M.B. personal communication). The potential origin of these kelp rafts represented an intriguing phenomenon that has impressed researchers in physiology and even algae

![Figure 5](image)

**Figure 5.** Relative contributions of the environmental variables to the models developed for *Macrocystis pyrifera* and *Durvillaea antarctica*, as percentage contribution and permutation importance.

**4. Discussion**

The arrival of *M. pyrifera* and *D. antarctica* on the Uruguay and southwestern coast of Brazil represented an intriguing phenomenon that has impressed researchers in physiology and even algae experts around the world (B.M.B. personal communication). The potential origin of these kelp rafts is more than 2000 km away, because the most likely and nearest well-documented occurrence, of both species, is the Falkland Islands [91]. The washed up plants, observed on the Uruguayan and Brazilian coasts showed that they have the physiological tools to acclimatize to the floating conditions in this area, during this period [92]. Despite a long drift process, the oceanographic and climatic conditions (cold water and reduced winter irradiance), observed during the end of the 2016 winter, could be responsible for the good physiological health of the *M. pyrifera* and *D. antarctica* rafts that washed up in Brazil [93]. Mature sporophylls from the *Macrocystis* rafts that washed up in Uruguay revealed the mechanism that promote connectivity among populations in the Southern Hemisphere and represent a source for colonization of the mapped suitable niches. The niche suitability, which was detected in all the regions that are subject to the Antarctic Circumpolar current, corroborated statements that indicated high connectivity among southern populations. Suitable temperature, irradiance and nutrient conditions, especially during the summer, enabled long-distance dispersion at this latitudinal range, as was hypothesized by Tala et al. [87] and reinforced here by our modeling evaluation.

It is essential to recognize that these species are known for their ability to travel long distances due to morphological structures, such as aerocysts, which provide buoyancy [39,45,94,95]. Studies involving passive dispersion of these species recorded distances of tens of kilometers [46,96]. Our data
indicate that *M. pyrifera* and *D. antarctica* potentially traveled a distance of at least 2700 km, reaching the Brazilian coast, still alive. Such evidence confirms that Macrocystis can grow and keep its reproductive viability while drifting for long periods at latitudes around 27° S during winter [92]. This high immigration capacity was shown by our physiological data, which demonstrated that raft chlorophyll fluorescence descriptors were similar to the sessile Chilean and North American populations [97]. An experiment by Hernández-Carmona et al. [46] showed that *M. pyrifera* still had viable zoospores after being adrift for 125 days and drifting for a distance of 890 km. This ability is sufficient to connect populations throughout a hemisphere, on a generational time scale, and may even facilitate gene flow between hemispheres under specific meteo-oceanographic conditions.

The floating specimens were found along the Brazilian coast during the last week of September 2016 (late Austral winter), approximately 13 days after the registration of a polar mesocyclone that reached the Argentinean, Uruguayan and Southern Brazilian coasts (Figure 6). Winds of up to 130 km/h were recorded in the coastal region of these countries and a sea level variation of up to 8 m high was recorded in Mar del Plata, Argentina (NOAA 2016). Considering the magnitude of this event and the relationship between extreme events and erosion of kelp forest structure, it is plausible that this storm produced the rafts and promoted the dispersal event. Storms and strong-wind events, such as extratropical cyclones, can detach canopy-forming kelps, transporting the rafts and immigrants, facilitating long-distance dispersal and transport of their propagules to suitable niches [25]. Furthermore, these storm and strong wind conditions can provide a pick-up/drop off process, and enhance the along-shelf current towards lower latitudes. This period of ideal conditions, with low temperatures and an enhanced northward current is observed at the end of Winter and late Spring in this region [98,99].

![Figure 6.](image-url)

*Figure 6.* (a) Images of the cyclone recorded on 13 September 2016, captured by the satellite GOES-16 (NOAA); (b) Confluence region (BMC) the Brazil (BC)—Malvinas Currents (MC) (Falklands). The colored lines are dynamic temporal mean of the dynamic height, taken between 1993 and 2013. They represent the major geostrophic current systems such as the BC, MC and NBC (North Brazilian Current). In this sense, currents flow parallel to the contours, with higher contours (yellow) on the left height. The intensity of the current is inversely proportional to the spacing between lines. (MDT,CNES-CLS13 was produced by CLS Space Oceanography Division and distributed by Aviso, with support from Cnes [http://www.aviso.altimetry.fr/]).

The CBM has an annual latitudinal dynamic, oscillating to the north during the Austral summer and to the south during the Austral winter [63]. Such variations can be attributed to the large scale
variability in the atmospheric forcing, mostly winds of the southern quadrant originating from the
Austral Winter [63]. There is an intensification of the Malvinas Current (CM), which carries Sub
Antarctic waters and brings energy to smaller latitudes of the Southern Atlantic [100]. Such patterns
can be verified in the SST satellite images of 2013, 2014 and 2015, the three years preceding the event
(Figure 2). Therefore, the intrusion of cold waters on the southwestern coast of Brazil can be considered
a common phenomenon during the Austral winter. However, in 2016, SST maps (Figure 2) showed
that, in addition to this cold-water intrusion, that reached lower latitudes, there were intrusions of
approximately 8 °C as well as one of approximately 12 °C. During the same period, and in the same
region, surface temperature anomalies were captured by the GOES-16 satellite (Figure 3).

Considering the floating and rafting nature of these species, they probably reached the coast
of Brazil driven by strong extratropical cyclone winds, and changes in the velocity and SST on the
surface coastal currents [64]. Moreover, the plume of the La Plata River (35°58′ S; 55°18′ W) along with
the south-northward coastal circulation, may have contributed to the dispersal of the individuals of
D. antarctica and M. pyrifera to the coastal region of southwestern Brazil. Nutrient enrichment from
rivers and upwelling feed the high demand of kelp species for nitrogen and phosphate [93], helping in
the resilience of rafts during the long drift.

The destination of floating algae, in medium and lower latitudes, is mainly determined by
the combination of abiotic and biotic factors (e.g., temperature currents, irradiation, and suitable
habitats) [45,101,102]. Rothäusler et al. (2011) showed that floating Macrocystis, at mid-latitudes,
(25° S–40° S) have a higher physiological adaptability and consequent ability to float for long periods
of time, and over long distances, surviving at temperatures ranging between 12 °C and 20 °C [45].
Experimentally they also showed that M. pyrifera could not withstand temperatures higher than 24 °C,
and specimens perished after 5 days. Nevertheless, in northern Baja California M. pyrifera populations
are exposed to SST variations of between 12.7 °C to 22.5 °C, while the southernmost subtropical
populations show warmer temperature tolerances varying between 15.6 °C to 25.5 °C [103]. It is
already well established that climate changes can affect substantially species distribution and, more
particularly, alter the rafts’ trajectory, which will influence the dispersal and distribution of marine
organisms [46,96,104]. Therefore, this aspect should be considered with particular attention.

Along the Brazilian coast, the algae were washed up at the beach and drifted in the breakwater
zone, which does not allow one to confirm whether these species inhabited the region. However,
the near-perfect prediction, indicating that at the spatial scale of our study, the environmental variables
used, explained the actual species distributions, and pose the discussion regarding distribution
extension [57]. The main predictors which influenced the models were variables related to PP,
temperature and, nutrient availability and light. Due to the physiological requirements and affinities
of the species known for low temperatures [45], we can confirm that maximum SST and bottom light
were the limiting factors for latitudinal and vertical distribution. Such a conclusion is evident when
we observe the georeferenced distribution of species restricted to environments in high and medium
latitudes in shallow areas, where the temperature and radiation were lower. The partial dependency
function shows that primary PP limits the distribution of Macrocystis and Durvillaea on its very
low levels, commonly observed in lower latitudes and deeper ocean regions. PP combines in a
single predictor the resource availability, involving irradiance, CO_2, temperatures and nutrients [105].
This shows the negative effect of oligotrophic regions and positive effect that upwelling and medium
latitudes regions have globally (e.g., [105]). The model (Figures 4 and 5) reinforces the sensitivity of
these species to changes in temperature, radiation and water quality (i.e., especially turbidity), because
these are the factors that delimit their geographical distribution [31,36]. However, it points towards
probable refuge regions, interestingly, in lower latitudes, far from regions previously recognized with
“optimum” environmental conditions, extrapolating their suitable habitats also to other temperate
regions in the Northern Hemisphere. The regional cooling of coastal environments observed in the
southwestern Atlantic warm temperate province southern edge [55,65] corroborate the niche suitability
described for the south of Brazil and Uruguay. The range extension of the South African kelp,
Ecklonia maxima, was also ascribed to a regional cooling process [56]. Therefore, kelps are ecosystem engineers, responsible for most of the primary production where they occur. This would mean that the spread or dispersal of kelps could have ecological, economical and sociological consequences.

In addition, it is likely that the ideal habitats for these species are located at deeper strata of the region. Studies report that some kelp species move to deeper water in a response to warming trends [33,106,107]. Species occurring in the tropics with high temperate affinities tend to occupy deeper niches [31], as is the case of Laminaria abyssalis, the only kelp-forming species ever recorded on the Brazilian coast [49]. Laminaria abyssalis is endemic to the Brazilian coast and has a specific biotope. It occurs on rhodolith beds (21° S and 40° W) at depths between 40 to 120 m, at temperatures of between 15–19 °C, and at low light intensity [108,109]. Due to the influence of SACW, deeper waters in southern Brazil are colder and is less variable when compared to surface [73] conditions, most of the time, optimal or tolerated for both kelp species.

Therefore, it is important to note that environmental variables used in the model are collected from the ocean surface. Considering deeper environments in the continental platform, it would be reasonable to assume that the probability of finding suitable habitats for these species would be even greater. Many suitable deeper refuges for these species can be identified, such as the Rio Grande rocky parcels at Rio Grande Sul State, southern Brazil, or Vitória Trindade seamounts, Espírito Santo State, southwestern Brazil. In these environments the topography of the seamounts can promote the upwelling of the cold nutrient rich waters, cooling and fertilizing the warmer, oligotrophic shallow waters [110], and in turn provide potentially ecophysiological conditions for the development of kelp spores or germlings [93]. We reinforce that the apparent absence of both species in areas with high habitat suitability is probably a consequence of absence or scarcity of sampling efforts. Therefore, suitability maps can be utilized in the definition of target areas for further surveys regarding kelp presence and kelp forest composition, diversity and connectivity.

However, populations of M. pyrifera may be limited not only by physical factors such as temperature, light and nutrients, but also by the type of substrate and the presence of herbivores (e.g., sea urchin species such as Loxechinus albus) [36]. Due to a lack of available herbivore data, on a global scale, among other important biological interactions, these biotic factors were not considered in our evaluations.

The introduction of benthic macroalgae is a frequent phenomenon in coastal regions [41,111]. Recently, the occurrence of Grateloupia turuturu Yamada was documented in the south-western Atlantic, more specifically on the coast of the state of Santa Catarina, in Brazil [112]. Despite its high potential as an invasive algae species in the world, G. turuturu has a higher affinity for temperate environments [112]. The species, which was first detected in the Southwestern Atlantic in 2011, can easily be found on the rocky shores near the point where the washed-up kelp rafts were found.

The effects of the arrival of kelp species such as M. pyrifera and D. antarctica in a new ern pacific populations have varied, over hundreds of kilometers along the Baja California unexpected environment is still not documented, although the southern limit of the northeastoria peninsula, during the past 20 years [113]. Migration is a fundamental process to increase resilience of populations, a natural part of an eco-evolutionary framework [61], where selective pressure variability meet phenotypic plasticity of the respective immigrant population. Therefore, if they are part of a natural dynamic equilibrium of marine environments these events should be better understood and preserved. Alternatively, if anthropogenic vectors promote it, these events must be evaluated under the usual bioinvasion perspective, and the management of this process should consider eradication. The kelp Undaria pinnatifida, also a canopy-forming kelp, is rated as the fifth most successful invasive species in the world [41,114]. However, studies have shown that where Ul. pinnatifida invaded there was no evidence of interspecific competition, except for small effects on the abundance of some species of intertidal communities [41,115]. Therefore, healthy forests of fucoids tend to resist invasions, unless the canopy is disturbed [116,117]. So far, there are no records on the effects of kelp-forming algae invading regions where no large algae forests occur.
The niche model results reinforce the need for transnational discussions regarding habitats, considered refuges for conservation initiatives in a global context of climate change intensification [118,119]. Such an environmental change could produce meteo-oceanographic events which could displace large amounts of kelp rafts over long distances. In addition to these events, ocean acidification could cause disturbances in underwater autochthonous communities, producing opportunities for kelp immigration that could change the resilience of eventual host communities [120]. Considering the importance of these organisms to coastal ecology (e.g., carbon fixation from the atmosphere, increasing habitat complexity and diversity) [31,121], these questions should be discussed at international forums and monitoring programs should be planned to consider possible origins and dispersal routes. These discussions should influence planning and the design, size and position of marine protected areas (MPA) that should add as potential services the preservation of species with this ability to survive long periods drifting.

5. Conclusions

The occurrence of these kelp rafts in the Brazilian and Uruguayan coast does not characterize the expansion of their limits of occurrence because settled populations were not found. However, such events could be regarded as an indication of change in climatic/oceanographic processes. Our results indicate that viable rafts can travel long distances, which demand a further discussion about long-term management of these immigration events. Therefore, changes in current temperatures and patterns may alter kelps raft routes and potential colonization areas. Considering the remarkable role that these rafts play in facilitating the dispersal and connectivity between coastal faunal and floristic communities, events such as this require greater attention regarding invasive species monitoring programs, niche conservation policies and climatic changes.
