Abstract: This study tackles a risk-limiting scheduling problem of non-renewable power generation for large power systems, and addresses potential violations of the security constraints owing to the volatility of renewable power generation and the uncertainty of load demand. To cope with the computational challenge that arises from the probabilistic constraints in the considered problem, a computationally efficient solution algorithm that involves a bisection method, an off-line constructed artificial neural network (ANN) and an on-line point estimation method is proposed and tested on the IEEE 118-bus system. The results of tests and comparisons reveal that the proposed solution algorithm is applicable to large power systems in real time, and the solution obtained herein is much better than the conventional optimal power flow (OPF) solution in obtaining a much higher probability of satisfying the security constraints.

Keywords: renewable power generation; demand response; risk-limiting scheduling; optimal power flow (OPF); security constraints; artificial neural network (ANN); point estimation method

1. Introduction

There is a growing interest in utilizing renewable energy such as wind and solar as the power generation sources to overcome the global climate change induced by carbon emission [1–4]. Additionally, the economic incentives based demand response has prevailed recently to improve the efficiency of electricity utilization and reduce carbon emission [5]. However, to integrate the distributed renewable energy sources and increase the participation of demand response, it is necessary to transform the traditional electricity grid into a smart grid [6]. The smart grid itself is simply the application of modern communication infrastructure to various segments of the electricity grid. However, the intermittency of the electricity supplied by renewable energy sources and the uncertain load demand caused by demand response in a modern power system require some traditional power system operations to consider these uncertainties [7,8]. For example, Dvorkin et al. [9] used a hybrid stochastic/interval approach to tackle the transmission-constrained unit commitment problem with uncertainties of wind power generation and load demand. Wu et al. [10] proposed a day-ahead stochastic scheduling model to cope with the hourly forecast errors of system loads and variable renewable sources. Ahmadi-Khatir et al. [11] proposed a decentralized method to optimally schedule generating units for systems under wind power uncertainties. Kusiak et al. discuss wind turbine capacity [12]. In this paper, the schedule of non-renewable power generation in a large power system with uncertain power generation and load demand is under consideration.

The challenge posed by uncertain power generation and load demand in scheduling the non-renewable power generation is to maintain the power balance at all times and satisfy the security constraints.
constraints on the security terms of interest, which are the bus voltage magnitude and the transmission line real power flow. In general, the scheduled value of optimal non-renewable power generation is the solution of optimal power flow (OPF), in which the renewable power generation and load demand are set to their predicted values, which differ from the actual values and cause a power mismatch in practice. Accordingly, the system operator should re-dispatch the scheduled optimal non-renewable power generation to maintain the power balance. This re-dispatch may cause the security constraints violated. Therefore, the purpose of this paper is to find a risk-limiting schedule of optimal non-renewable power generation to reduce the probability of violating security constraints after the re-dispatch in the presence of uncertain power generation and load demand. In past decades, numerous mathematical programming methods for solving deterministic OPF problems of the traditional electricity grid were proposed. For example, the successive linear programming method [13], the successive quadratic programming method [14], the Lagrange Newton method [15], the primal-dual interior point method [16], the dual-type method [17], the multi-objective programming method [18], the hybrid algorithm [19], the modified shuffle frog leaping (SFL) algorithm [20], the population based algorithm [21], etc. However, the aforementioned methods cannot be used to solve the problem considered in this paper.

Setting restrictive bounds for the security constraints in the OPF problem formulation can reduce the risk of violating the security constraints in practice; however, more restrictive bounds result in a larger scheduled optimal non-renewable power generation cost. Therefore, to minimize the scheduled optimal non-renewable power generation cost, the problem formulation of the proposed risk-limiting schedule of optimal non-renewable power-generation (RSONP) is to determine the least restrictive bounds that yield the required probability of satisfying the security constraints after the re-dispatch. Few articles have discussed this issue. Although Varaiya et al. [22] proposed a dispatch method with limiting risk, they ignored security constraints and considered only the need for power generation to satisfy load demand. Attaching a probability to the satisfaction of security constraints, Zhang and Li [23] developed a chance constrained programming (CCP) method for solving OPF with load uncertainty. Lin and Lin [24] proposed a risk-limiting OPF (RLOPF) method to solve the RLOPF problem for systems with a high penetration of wind power; however, they did not take into account the uncertainty of load demand. Therefore, the RSONP problem with uncertain power generation and load demand remains unsolved. Furthermore, both the CCP method and the RLOPF method were experimentally tested using small systems [23,24]. Hence, the contribution of this paper is to propose a computationally efficient RSONP algorithm to solve the RSONP problem of a large power system.

This paper is organized as follows. Section 2 presents the method for solving the RSONP problem. Section 3 presents the test results and discussions. Section 4 presents the conclusions and further research.

2. Method

For simplicity of presentation, the only renewable energy source considered herein is wind. However, solar power can be easily included in the formulated RSONP problem and the proposed RSONP algorithm.

2.1.1. Conventional Optimal Power Flow Problem

The OPF problem has various formulations. In this paper, the following conventional optimal power flow (COPF) problem is considered [8].
\[
\min_{u_G, \hat{u}_G \in G \backslash WG} \sum_{G \in G \backslash WG} a_i p_G^2 + b_i p_G + c_i
\]
subject to:
\[
g(x, u_G, \hat{u}_W, \hat{u}_D) = 0
\]
\[
p_{ij}^o \leq p_{ij}(x, x_i) \leq \bar{p}_{ij}, \forall (i, j) \in L
\]
\[
V_i^o \leq V_i \leq V_i^o, \ i = 1, \ldots, N
\]
\[
u_G^i \leq u_G^i \leq \pi_G^i, \forall i \in G \backslash WG
\]

where \( V_i^o \leq V_i \leq V_i^o, \ i = 1, \ldots, N, \) and \( p_{ij}^o \leq p_{ij}(x, x_i) \leq \bar{p}_{ij}, \forall (i, j) \in L \) represent the set of security constraints with normal bounds; and \( u_G^i \leq u_G^i \leq \pi_G^i \) represents the power generation constraint at bus \( i. \) Normally, \( V_i^o = 0.95, V_i^o = 1.05 \) and \( p_{ij}^o = -\bar{p}_{ij}. \) For notational simplicity, the aforementioned security constraints are rewritten as \( h_j^o \leq h_j(x) \leq \bar{h}_j, j = 1, \ldots, m, \) where \( m = N + |L|, \) and \( |L| \) is the total number of transmission lines, so \( m \) is the total number of security constraints. Notably, \( h_j^o = -\bar{h}_j \) for the transmission line real power flow, and the renewable power generation is assumed to have no cost.

2.1.2. Statement of Risk-Limiting Schedule of Optimal Non-Renewable Power-Generation Problem

As indicated in Section 1, the RSONP problem is to determine the least restrictive bounds for security constraints in the OPF problem formulation that yield the required probability \( \eta \) that the security constraints will be satisfied in practice as follows:

\[
\min \sum_{j=1}^{m} \left( (h_j^o - h_j^s)^2 + (\bar{h}_j - \bar{h}_j^o)^2 \right)
\]
subject to:
\[
\text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq \bar{h}_j^o | h_j^s, \bar{h}_j^o, \tilde{x} \} \geq \eta, \ j = 1, \ldots, m
\]

where \( \tilde{x} \) represents the random state-vector after re-dispatching (RSAR), which is resulted from the scheduling and re-dispatching stages that will be presented later. \( \text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq \bar{h}_j^o | h_j^s, \bar{h}_j^o, \tilde{x} \} \) represents the conditional probability of satisfying the \( j \)th security constraint after the re-dispatch for the given restrictive bounds \( (h_j^s, \bar{h}_j^o), \) and the objective function is the distance between the restrictive bounds \( (h_j^s, \bar{h}_j^o) \) and the normal bounds \( (h_j^o, \bar{h}_j^o). \) Therefore, the RSONP problem is to find the \( (h_j^s, \bar{h}_j^o) \) that is closest to \( (h_j^o, \bar{h}_j^o) \) while satisfying the conditional probability constraints in Equation (2).

2.1.3. Monte Carlo Simulation Procedures for Evaluating Exact Conditional Probability of Satisfying Security Constraints

For the given \( (h_j^s, \bar{h}_j^o), \) the procedures to evaluate the exact value of \( \text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq \bar{h}_j^o | h_j^s, \bar{h}_j^o, \tilde{x} \} \) are described below.

- Scheduling Stage

In the scheduling stage, both wind power generation and load demand are set to their predicted values in the OPF problem with restrictive bounds \( (h_j^s, \bar{h}_j^o) \) (OPFPRB), which is expressed as Equation (3).

\[
\min_{u_G, \hat{u}_G \in G \backslash WG} \sum_{G \in G \backslash WG} a_i p_G^2 + b_i p_G + c_i
\]
subject to:
\[
g(x, u_G, \hat{u}_W, \hat{u}_D) = 0
\]
\[
h_j^s \leq h_j(x) \leq \bar{h}_j, j = 1, \ldots, m
\]
\[
u_G^i \leq u_G^i \leq \pi_G^i, \forall i \in G \backslash WG
\]

The solution of OPFPRB is denoted by \( u_G^{*}, \forall i \in G \backslash WG, \) and is called the scheduled optimal non-renewable power-generation (SONP) for the given restrictive bounds \( (h_j^s, \bar{h}_j^o). \)
• Random Generation of Wind Speed and Load Demand

The wind speed $v_l$ is a random variable, so is the wind power generation $u_{W_l}(v_l)$. Although the actual load demand for all buses, $u_{D_l}$, $l = 1, \ldots, N_l$, are also random variables, the variations of small load demand can be neglected relative to those of large load demand. Therefore, large load demand can be regarded as random variables and the corresponding buses and load demand can be re-indexed as $u_{D_l}$, $\tilde{u}_{D_l}$, $\tilde{u}_{NL}$. The vector of small load demand is set to the predicted vector $u_{D_l}$. Based on $p(v_l)$ and $p(\tilde{P}_{D_l})$, $v_l$ and $\tilde{P}_{D_l}$ can be randomly generated. Subsequently, the wind power generation $\tilde{u}_{W_l}(v_l) = [\tilde{P}_{W_l}(v_l), \tilde{Q}_{W_l}(v_l)]^T$ can be calculated based on the randomly generated $v_l$ by:

$$\tilde{P}_{W_l}(v_l) = 0.5C_p a v_l^3 A$$

$$\tilde{Q}_{W_l}(v_l) = \tilde{P}_{W_l}(v_l) \tan \phi_l$$

where $a$, $A$ and $C_p$ represent the air density, cross-section swept by wind turbine blade and the power coefficient, respectively; $\phi_l$ represents the phase angle in the power factor cos $\phi_l$ of the wind power generation. The reactive load demand $\tilde{Q}_{D_l}$ can be obtained based on the randomly generated $\tilde{P}_{D_l}$ by:

$$\tilde{Q}_{D_l} = \tilde{P}_{D_l} \tan \phi_{D_l}$$

where $\phi_{D_l}$ is the phase angle of the load power factor cos $\phi_{D_l}$. Then, we can have the large load demand $\tilde{u}_{D_l} = [\tilde{P}_{D_l}, \tilde{Q}_{D_l}]^T$.

• Re-dispatching Stage

$\tilde{u}_{W_l}(v_l)$ and $\tilde{u}_{D_l}$ differ from their predicted values $u_{W_l}$ and $u_{D_l}$, respectively. The total power generation deviation $\sum_{l \in WG} \tilde{u}_{W_l}(v_l) - u_{W_l}$, the total large load-demand deviation $\sum_{l = 1}^{N_l} \tilde{u}_{D_l} - u_{D_l}$ and the deviation of the system’s total real and reactive line losses, which are denoted by $\Delta P_{loss}$ and $\Delta Q_{loss}$, respectively, can be compensated by re-dispatching the SONP $u_{G_i}^{s*}$, $\forall i \in G \setminus WG$, using available economic dispatch (ED) method [25], such that:

$$- (\sum_{l \in WG} \tilde{P}_{W_l}(v_l) - \tilde{P}_{W_l}) + (\sum_{l = 1}^{N_l} \tilde{P}_{D_l} - \tilde{P}_{D_l}) + \Delta P_{loss} = \sum_{i \in G \setminus WG} P_{G_i}^{s*} r_P \%$$

$$- (\sum_{l \in WG} \tilde{Q}_{W_l}(v_l) - \tilde{Q}_{W_l}) + (\sum_{l = 1}^{N_l} \tilde{Q}_{D_l} - \tilde{Q}_{D_l}) + \Delta Q_{loss} = \sum_{i \in G \setminus WG} Q_{G_i}^{s*} r_Q \%$$

Then, in the re-dispatching stage, the SONP $u_{G_i}^{s*}$, $\forall i \in G \setminus WG$, is re-dispatched as the Non-renewable Power-generation After Re-dispatching (NPAR) $\tilde{u}_{G_i}^{s*}$, $\forall i \in G \setminus WG$, for the given restrictive bounds ($\mathbf{h}^s$, $\mathbf{H}^s$) by:

$$\tilde{P}_{G_i} = P_{G_i}^{s*} (1 + r_P \%)$$

$$\tilde{Q}_{G_i} = Q_{G_i}^{s*} (1 + r_Q \%)$$

The RSAR $\tilde{x}^s$ in Equation (2) can be obtained by solving the following power flow balance equation in terms of the re-dispatched NPAR $\tilde{u}_{G_i}$, the randomly generated $\tilde{u}_W$, the randomly generated $\tilde{u}_{D_l}$ and the predicted small load demand $\tilde{u}_{DS}$:

$$g(\tilde{x}^s, \tilde{u}_G, \tilde{u}_W, \tilde{u}_{D_l}, \tilde{u}_{DS}) = 0$$

Subsequently, the security term after re-dispatching (STAR), $h_j(\tilde{x}^s)$, for the given restrictive bounds ($\mathbf{h}^s$, $\mathbf{H}^s$) can be evaluated for $j = 1, \cdots, m$; this re-dispatching stage associated with the
randomly generated $\tilde{v}_j$ and $\tilde{y}_j$ is repeated 10,000 times to carry out the Monte Carlo simulation (MCS), and 10,000 samples of $h_j(\tilde{x})$ can be obtained for each $j = 1, \cdots, m$.

- Evaluating Exact $\text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq h_j^s, h_j^s\}$

Based on the obtained 10,000 samples of $h_j(\tilde{x})$, the exact value of $\text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq h_j^s, h_j^s\}$ can be calculated by $\text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq h_j^s, h_j^s\} = (\text{number of samples of } h_j(\tilde{x}) \text{ satisfying the security constraints})/10,000$.

Because MCS is too computational time consuming, the first computational challenge of the RSONP problem (Equation (2)) is to determine the feasibility of $(h_j^s, h_j^s)$ that is defined as the satisfaction of the inequality constraints in Equation (2). Accordingly, the second computational challenge is to develop a computationally efficient algorithm to solve the RSONP problem (Equation (2)) for the optimal restrictive bounds $(h_j^{s*}, h_j^{s*})$ and the associated optimal SONP (OSONP) $h_j^{s*}, \forall i \in G\setminus WG$, which is the optimal solution to the OPFPRB (Equation (3)) when $(h_j^s, h_j^s) = (h_j^{s*}, h_j^{s*})$, in real time for a large system.

2.2. Risk-Limiting Schedule of Optimal Non-Renewable Power-Generation Algorithm

- Sufficient Conditions for Feasibility of $(h_j^s, h_j^s)$

The RSONP problem (Equation (2)) is separable, and it can be decomposed into the following $m$ independent sub-problems.

For $j = 1, \cdots, m$,

$$\min_{h_j^s, h_j^s} (h_j^s - h_j^s)^2 + (\bar{h}_j - \tilde{h}_j)^2$$

subject to:

$$\text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq h_j^s, h_j^s\} \geq \eta \quad (12)$$

Accordingly, the optimal solution $(h_j^{s*}, h_j^{s*})$ to the RSONP problem (Equations (2) or (12)) is defined such that:

$$\text{Prob}\{h_j^s \leq h_j(\tilde{x}) \leq h_j^s, h_j^s\} = \eta \quad (13)$$

for $j = 1, \cdots, m$. Notably, both variables $h_j^s$ and $\bar{h}_j$ have the same feasible region $[\tilde{h}_j^{s*}, \bar{h}_j^{s*}]$ and satisfy $h_j^s < \tilde{h}_j$, $h_j^{s*} > h_j^s$ and $\bar{h}_j^{s*} < \bar{h}_j$. Therefore, $\tilde{h}_j$ and feasible $\bar{h}_j$ are located on the right-hand side and the left-hand side of $\bar{h}_j^{s*}$, respectively. Similarly, $h_j^s$ and feasible $\bar{h}_j^{s*}$ are located on the left-hand side and the right-hand side of $h_j^{s*}$, respectively.

The $\eta$-upper and $\eta$-lower bounds of $h_j(\tilde{x})$ are denoted by $\bar{y}_j$ and $\tilde{y}_j$, respectively. For the bus voltage magnitude, $\bar{y}_j$ and $\tilde{y}_j$ are defined by:

$$\langle \bar{y}_j \tilde{y}_j \rangle = \text{arg} \left[ \min_{\bar{y}_j, \tilde{y}_j} \text{Prob}\{y_j \leq h_j(\tilde{x}) \leq \bar{y}_j, \tilde{y}_j\} = \eta \right] \quad (14)$$

However, for the transmission-line real-power flow, an additional constraint $y_j = -\bar{y}_j$ must be imposed on the minimization problem that is specified on the right-hand side of Equation (14). Hence, $(\bar{y}_j, \tilde{y}_j)$ is a function of $(h_j^s, h_j^s)$ and can also be written as $(\bar{y}_j(h_j^s, h_j^s), \tilde{y}_j(h_j^s, h_j^s))$. 
It can be easily proved that if \( \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) \leq \bar{y}_{jn} \) and \( y_{jn}(\bar{h}^s, \bar{h}^o) \geq h_j^o \), then \( \text{Prob}(h_j^o \leq h_j(\bar{x}^o) \leq h_j^o) \) holds. Therefore, \( \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) \leq \bar{y}_{jn} \) and \( y_{jn}(\bar{h}^s, \bar{h}^o) \geq h_j^o \) for \( j = 1, \ldots, m \) represent sufficient conditions for the feasibility of \( (\bar{h}^s, \bar{h}^o) \).

- Bisection Method

Based on the above analysis, \( \bar{h}_j^{m+} \) and \( h_j^o \) are the closest points to \( \bar{h}_j^{o-} \) and \( h_j^o \), respectively, among all points in the corresponding feasible region. Accordingly, a bisection method can be used to identify \( \bar{h}_j^{m+} \) and \( h_j^o \) based on \( \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) \) and \( y_{jn}(\bar{h}^s, \bar{h}^o) \) as follows. Let \( UB(\bar{h}_j^{m+}) \) and \( LB(\bar{h}_j^{m+}) \) be a strict upper-bound and a strict lower-bound on \( \bar{h}_j^{m+} \), respectively, such that \( UB(\bar{h}_j^{m+}) \) is an infeasible \( h_j^o \) but \( LB(\bar{h}_j^{m+}) \) is a feasible \( \bar{h}_j^{m+} \). Similarly, let \( UB(h_j^o) \) and \( LB(h_j^o) \) be a strict upper-bound and a strict lower-bound on \( h_j^o \), respectively, such that \( UB(h_j^o) \) is a feasible \( h_j^o \) but \( LB(h_j^o) \) is an infeasible \( h_j^o \). For the given \( UB(\bar{h}_j^{m+}) \), \( LB(\bar{h}_j^{m+}) \), \( UB(h_j^o) \) and \( LB(h_j^o) \), setting:

\[
\bar{h}_j^{m+} = \frac{UB(\bar{h}_j^{m+}) + LB(\bar{h}_j^{m+})}{2}
\]

\[
h_j^o = \frac{UB(h_j^o) + LB(h_j^o)}{2}
\]

for \( j = 1, \ldots, m \) and evaluating \( \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) \) and \( y_{jn}(\bar{h}^s, \bar{h}^o) \) for \( j = 1, \ldots, m \), enable \( UB(\bar{h}_j^{m+}) \), \( LB(\bar{h}_j^{m+}) \), \( UB(h_j^o) \) and \( LB(h_j^o) \) to be updated as:

\[
UB(\bar{h}_j^{m+}) = \bar{h}_j^{m+} \text{ if } \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) > \bar{h}_j^{m+}
\]

\[
LB(\bar{h}_j^{m+}) = \bar{h}_j^{m+} \text{ if } \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) \leq \bar{h}_j^{m+}
\]

\[
UB(h_j^o) = h_j^o \text{ if } y_{jn}(\bar{h}^s, \bar{h}^o) \geq h_j^o
\]

\[
LB(h_j^o) = h_j^o \text{ if } y_{jn}(\bar{h}^s, \bar{h}^o) < h_j^o
\]

based on the sufficient conditions for the feasibility of \( (\bar{h}^s, \bar{h}^o) \). Notably, the evaluation of both \( \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) \) and \( y_{jn}(\bar{h}^s, \bar{h}^o) \) for the given \( (\bar{h}^s, \bar{h}^o) \) for \( j = 1, \ldots, m \) are presented in the following section. The above iterative bisection method terminates when both \( UB(\bar{h}_j^{m+}) - LB(\bar{h}_j^{m+}) < \varepsilon \) and \( UB(h_j^o) - LB(h_j^o) < \varepsilon \) hold, where \( \varepsilon \) is a small positive real number, and the final \( LB(\bar{h}_j^{m+}) \) and \( UB(h_j^o) \) are the solutions for \( \bar{h}_j^{m+} \) and \( h_j^o \), respectively, for \( j = 1, \ldots, m \).

2.2.2. Evaluating \( \eta \)-Upper and \( \eta \)-Lower Bounds of \( h_j(\bar{x}^o) \)

To carry out the bisection method presented above, the \( \bar{y}_{jn}(\bar{h}^s, \bar{h}^o) \) and \( y_{jn}(\bar{h}^s, \bar{h}^o) \) for the given \( (\bar{h}^s, \bar{h}^o) \) need to be evaluated first for \( j = 1, \ldots, m \). For this purpose, a two-stage approach is presented in this section.

The two-stage approach consists of an off-line stage and an on-line stage. In the off-line stage, the functional relationship between \( (\bar{y}_{jn}(\bar{h}^s, \bar{h}^o), y_{jn}(\bar{h}^s, \bar{h}^o)) \) and \( (\mu_{h_j}, \sigma_{h_j}) \) for a large range of \( (\bar{h}^s, \bar{h}^o) \) is constructed using an artificial neural network (ANN) for each \( j = 1, \ldots, m \), where \( \mu_{h_j} \) and \( \sigma_{h_j} \) represent the mean and standard deviation of \( h_j(\bar{x}^o) \) for the given \( (\bar{h}^s, \bar{h}^o) \). In the on-line stage, \( (\mu_{h_j}, \sigma_{h_j}) \) will be evaluated for the given \( (\bar{h}^s, \bar{h}^o) \). In general, to obtain the exact \( (\mu_{h_j}, \sigma_{h_j}) \) of \( h_j(\bar{x}^o) \) for the given \( (\bar{h}^s, \bar{h}^o) \), MCS is required. However, MCS is too time consuming to be used on-line. Therefore, a \( 2K + 1 \) point estimation method is used to evaluate \( (\mu_{h_j}, \sigma_{h_j}) \) of \( h_j(\bar{x}^o) \) for the given \( (\bar{h}^s, \bar{h}^o) \) on-line. Thus, for the given \( (\bar{h}^s, \bar{h}^o) \), once the corresponding \( (\mu_{h_j}, \sigma_{h_j}) \) of \( h_j(\bar{x}^o) \) is obtained on-line, it will be input to the
off-line constructed ANN, and whose output is the \((y_m(h^s, \vec{h}^s), y_m(h^t, \vec{h}^t))\) needed in the bisection method. In the following, the ANN and the \(2K + 1\) point estimation method are presented.

- **ANN Model for Input–Output Relationship between \((\mu_{h}, \sigma_{h})\) and \((\overline{y}_{m}(h^s, \vec{h}^s), \overline{y}_{m}(h^t, \vec{h}^t))\)**

In the off-line stage, for each \(j = 1, \cdots, m\), an easily implementable feed-forward back propagation ANN [26,27], which comprises an input layer, a hidden layer and an output layer, is used to establish the input–output relationship between \((\mu_{h}, \sigma_{h})\) and \((\overline{y}_{m}(h^s, \vec{h}^s), \overline{y}_{m}(h^t, \vec{h}^t))\) for a large range of \((h^s, \vec{h}^s)\).

Figure 1 shows this three-layer ANN that consists of two input neurons, \(q\) hidden-layer neurons and two output neurons, where \(\omega_{\mu}, i = 1, 2, l = 1, \cdots, q\) and \(\gamma_{\mu k}, k = 1, 2\) are the arc weights. The inputs to the two neurons in the input layer are \(\mu_{h_{j}}\) and \(\sigma_{h_{j}}\), and the outputs of the two output neurons are \(\overline{y}_{m}(h^s, \vec{h}^s)\) and \(\overline{y}_{m}(h^t, \vec{h}^t)\).

The neurons in the input layer directly distribute \(\mu_{h_{j}}\) and \(\sigma_{h_{j}}\) to the neurons in the hidden layer. The hyperbolic tangent sigmoid function given in Equation (21) is utilized as the activation function of the neurons in the hidden layer [26]:

\[
\tanh h(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \tag{21}
\]

The activation function in the output layer is a linear function, which sums all the weighted outputs of the hidden layer.

Each of the \(m\) ANNs is trained off-line in two steps, which are the collection of training data set and training the ANN.

![Figure 1. Three-layer artificial neural network (ANN).](image)

- **Collecting Training Data Set**

In addition to a large range of \((h^s, \vec{h}^s)\), a wide range of parameters of \(p(v_i)\) and \(p(P_{DL}^i)\) should be considered to cover a wide range of applications. For example, if \(p(v_i)\) is of a Weibull distribution, it can be described by Equation (22):

\[
p(v_i) = \frac{\beta}{\alpha} \left(\frac{v_i}{\alpha}\right)^{\beta-1} e^{-\left(\frac{v_i}{\alpha}\right)^{\beta}} \tag{22}
\]

where the parameters \(\alpha\) and \(\beta\) are the scale and shape coefficients, respectively, then wide ranges of \(\alpha\) and \(\beta\) will be considered. Similarly, if \(p(P_{DL}^i)\) is of a normal distribution, it can be described by Equation (23):

\[
p(P_{DL}^i) = \frac{1}{\sigma_{DL}^i \sqrt{2\pi \epsilon}} e^{-\frac{(P_{DL}^i - \mu_{DL}^i)^2}{2\sigma_{DL}^i^2}} \tag{23}
\]
where the parameters $\mu_{D_l}$ and $\sigma_{D_l}$ are the mean and the standard deviation of $P_{D_l}$, then wide ranges of $\mu_{D_l}$ and $\sigma_{D_l}$ will be considered. Based on these premises, the procedure for collecting training data set can be described as follows.

**Step Co1:** Randomly select a sample of $(\mathbf{h}^*, \mathbf{h}^s)$, $\alpha$, $\beta$, $\mu_{D_l}$ and $\sigma_{D_l}$.

**Step Co2:** For $j = 1, \ldots, m$, use the MCS that is described in Section 2.1.3 to obtain 10,000 samples of $h_i(\mathbf{x}^s)$ to compute $\mu_{h_i}$ and $\sigma_{h_i}$, and determine the $\overline{y}_{j,m}(\mathbf{h}^*, \mathbf{h}^s)$ and $y_{j,m}(\mathbf{h}^*, \mathbf{h}^s)$ based on Equation (14); the obtained ($\mu_{h_i}, \sigma_{h_i}$) and ($\overline{y}_{j,m}(\mathbf{h}^*, \mathbf{h}^s), y_{j,m}(\mathbf{h}^*, \mathbf{h}^s)$) form a pair of input and output data of $h_i(\mathbf{x}^s)$.

**Step Co3:** Repeat Steps Co1-Co2 $M$ times, where $M = 16,512$. Then, for $j = 1, \ldots, m$, $M$ pairs of input output data that are $(\mu_{h_i}^{(j)}, \sigma_{h_i}^{(j)})$ and $(\overline{y}_{j,m}(\mathbf{h}^*, \mathbf{h}^s), y_{j,m}(\mathbf{h}^*, \mathbf{h}^s))$, $i = 1, \ldots, M$, can be obtained as the training data set, where $(\mu_{h_i}^{(j)}, \sigma_{h_i}^{(j)})$ and $(\overline{y}_{j,m}(\mathbf{h}^*, \mathbf{h}^s), y_{j,m}(\mathbf{h}^*, \mathbf{h}^s))$ represent the $(\mu_{h_i}, \sigma_{h_i})$ and $(\overline{y}_{j,m}(\mathbf{h}^*, \mathbf{h}^s), y_{j,m}(\mathbf{h}^*, \mathbf{h}^s))$ of $h_i(\mathbf{x}^s)$, respectively, obtained based on the $i$th randomly selected sample of $(\mathbf{h}^*, \mathbf{h}^s)$, $(\alpha, \beta)$ and $(\mu_{D_l}, \sigma_{D_l})$.

- **Training $m$ ANNs**

  For a given input $(\mu_{h_i}^{(j)}, \sigma_{h_i}^{(j)})$ to the $j$th ANN that is shown in Figure 1, let the corresponding output be $\overline{z}_{j,m}^{(j)}((\mu_{h_i}^{(j)}, \sigma_{h_i}^{(j)}), \omega, \gamma)$ and $z_{j,m}^{(j)}((\mu_{h_i}^{(j)}, \sigma_{h_i}^{(j)}), \omega, \gamma)$, given by the following Equations:

  $$
  \overline{z}_{j,m}^{(j)} = \frac{1}{d} \sum_{l=1}^{d} \gamma_{1,l} \tan h(\omega_{1,l} \mu_{h_i}^{(j)} + \omega_{2,l} \sigma_{h_i}^{(j)})
  $$

  $$
  z_{j,m}^{(j)} = \frac{1}{d} \sum_{l=1}^{d} \gamma_{2,l} \tan h(\omega_{1,l} \mu_{h_i}^{(j)} + \omega_{2,l} \sigma_{h_i}^{(j)})
  $$

  where $\gamma = [\gamma_{1,1}, \cdots, \gamma_{q,1}, \gamma_{1,2}, \cdots, \gamma_{q,2}]^T$ and $\omega = [\omega_{1,1}, \cdots, \omega_{1,q}, \omega_{2,1}, \cdots, \omega_{2,q}]^T$ are vectors of the arc weights of the $j$th ANN. The training problem for the $j$th ANN is to find $\omega$ and $\gamma$ that minimize the mean square error (MSE):

  $$
  \min_{\omega, \gamma} \frac{1}{M} \sum_{m=1}^{M} (\overline{y}_{j,m}(\mathbf{h}^*, \mathbf{h}^s) - \overline{z}_{j,m}^{(j)})^2 + (y_{j,m}(\mathbf{h}^*, \mathbf{h}^s) - z_{j,m}^{(j)})^2
  $$

  based on the $j$th training data set $((\mu_{h_i}^{(j)}, \sigma_{h_i}^{(j)}), (\overline{y}_{j,m}(\mathbf{h}^*, \mathbf{h}^s), y_{j,m}(\mathbf{h}^*, \mathbf{h}^s)))$, $i = 1, \ldots, M$. The Levenberg-Marquardt algorithm [28] is used herein as the iterative training algorithm for solving Equation (26). This training algorithm is terminated when either of the following two conditions is met: (i) MSE is less than 0.01; or (ii) the number of epochs exceeds 5000.

- **2K+1 point estimation method for estimating mean and standard deviation of $h_i(\mathbf{x}^s)$**

  As indicated previously, it is too computational time consuming to evaluate $\mu_{h_i}$ and $\sigma_{h_i}$ of $h_i(\mathbf{x}^s)$ using MCS. Therefore, the goal of 2K+1 point estimation method is to evaluate $\mu_{h_i}$ and $\sigma_{h_i}$ of $h_i(\mathbf{x}^s)$ for the given $(\mathbf{h}^*, \mathbf{h}^s)$ in real time. Suppose that $|WG| + N^L = K$, where $|WG|$ is the total number of wind power generation bases, $h_i(\mathbf{x}^s)$ is a random function of $K$ input random variables, then the employed 2K+1 point estimation method [7,24,29] can be described below.

  First, the considered random variables are re-named and re-indexed, such that the random wind speeds $v_l, \forall l \in WG$, are re-named and re-indexed as $z_k, k = 1, \ldots, |WG|$, and the $N$ random large real load demands $P_{D_l}, l = 1, \ldots, N^L$ as $z_k, k = |WG| + 1, \ldots, K$. The 2K+1 point estimation method calculates 2K pairs of $(z_{k,n}, \omega_{k,n})$, $k = 1, \ldots, K, n = 1, 2$ first, where the location $z_{k,n}$ and the weighting factor $\omega_{k,n}$ are the $n$th concentration of the random variable $z_k$,
and can be calculated as follows. Let \( \mu_{z_k} = E[z_k] \) and \( \sigma^2_{z_k} = E[(z_k - \mu_{z_k})^2] \); \( \mu_{z_k} \) and \( \sigma^2_{z_k} \) can be calculated based on the pdf \( p(z_k) \), which is either \( p(v_l) \) or \( p(P_{D_l}) \). For \( k = 1, \cdots, K, n = 1, 2, 3, 4 \), where the standard point \( \tau_{k,n} = \frac{\lambda_{k,n}}{\mu_{z_k}} + (-1)^{3-n} \frac{\lambda_{k,4} - \frac{3}{4}\lambda_{k,2}^2}{\frac{3}{2}\lambda_{k,3}} \), and the skewness \( \lambda_{k,3} \) and kurtosis \( \lambda_{k,4} \) are obtained based on \( \lambda_{k,j} = M_j(z_k) \) and \( M_j(z_k) = \int_{-\infty}^{\infty} (z_k - \mu_{z_k})^j p(z_k) dz_k \) for \( j = 3, 4 \). For \( k = 1, \cdots, K, n = 1, 2, 3, 4 \), the weighting factor \( w_{k,n} = \frac{(-1)^{3-n}}{\tau_{k,1} \tau_{k,2} - \tau_{k,3} \tau_{k,4}} \). Once the 2K pairs of \( (z_{k,n}, w_{k,n}) \), \( k = 1, \cdots, K, n = 1, 2, 3, 4 \) are obtained, then for a given \( (h^*, \hat{h}^*) \), the \( h_i(\hat{x}^*) \) is evaluated twice for each random variable \( z \) at the two points made up of the 4th location \( z_{k,n} \) of \( z_k \) and the mean \( \bar{z}_k \) for the rest \( K - 1 \) \( z_k \), which are \( (\bar{z}_1, \cdots, \bar{z}_{k-1}, z_{k,n}, \bar{z}_{k+1} \cdots, \bar{z}_K) \), \( n = 1, 2, 3, 4 \), rather than the 10,000 times in the MCS. The weighting factor \( w_{k,n} \) specifies the relative importance of the evaluation of \( h_i(\hat{x}^*) \) at the point \( \bar{z}_1, \cdots, \bar{z}_{k-1}, z_{k,n}, \bar{z}_{k+1} \cdots, \bar{z}_K \). These 2K evaluations of \( h_i(\hat{x}^*) \) and an evaluation at the point \( (\bar{z}_1, \cdots, \bar{z}_{k-1}, z_{k,n}, \bar{z}_{k+1} \cdots, \bar{z}_K) \) that is associated with a weighting factor \( w_{0,3} \) constitute the 2K + 1 evaluations of \( h_i(\hat{x}^*) \), where \( w_{0,3} = \sum_{k=1}^{K} \left( 1 - \frac{1}{\lambda_{k,4} \lambda_{k,3}} \right) \). Then, \( \mu_{h_i} \) and \( \sigma^2_{h_i} \) can be estimated from the above 2K + 1 evaluations of \( h_i(\hat{x}^*) \) and the corresponding \( w_{k,n} \) by:

\[
\mu_{h_i} = \sum_{k=1}^{K} \sum_{n=1}^{2} w_{k,n} h_i(\hat{x}^* (z_{k,n})) + w_{0,3} h_i(\hat{x}^* (z_{0,3}))
\]

\[
\sigma^2_{h_i} = \left( \sum_{k=1}^{K} \sum_{n=1}^{2} w_{k,n} h_i(\hat{x}^* (z_{k,n})) \right)^2 + w_{0,3} h_i(\hat{x}^* (z_{0,3}))^2 - \mu_{h_i}^2
\]

The advantage of 2K + 1 point estimation method is that it uses just 2K + 1 evaluations to evaluate the \( \mu_{h_i} \) and \( \sigma^2_{h_i} \) of \( h_i(\hat{x}^*) \) for the given \( (h^*, \hat{h}^*) \) rather than using the 10,000 evaluations that are required in the MCS; therefore, it can be utilized in real-time applications. Clearly, estimating \( \sigma^2_{h_i} \) yields an estimate of \( \sigma_{h_i} \). Once \( \mu_{h_i} \) and \( \sigma_{h_i} \) of \( h_i(\hat{x}^*) \) for the given \( (h^*, \hat{h}^*) \) are estimated, they can be input to the \( j \)th ANN that is constructed off-line, and whose outputs are the estimated \( \tilde{y}_{j,n}(h^*, \hat{h}^*) \) and \( y_{j,n}(h^*, \hat{h}^*) \) of \( h_i(\hat{x}^*) \).

2.2.3. Risk-Limiting Schedule of Optimal Non-Renewable Power-Generation Algorithm

- **Initial Setting of Bounds**

In the bisection method, the initial values of the four bounds \( UB(\hat{h}^*_{j,l}) \), \( LB(\hat{h}^*_{j,l}) \), \( UB(h^*_{j,l}) \) and \( LB(h^*_{j,l}) \) must first be specified. With respect to the transmission line real power flow, since \( \hat{h}^*_{j,l} > h^*_{j,l} \), \( h^*_{j,l} = -\hat{h}^*_{j,l} \) and \( |p_{ij}| \geq 0 \), the initial values of these four bounds can be set to \( UB(\hat{h}^*_{j,l}) = \hat{h}^*_{j,l}, LB(\hat{h}^*_{j,l}) = 0, UB(h^*_{j,l}) = 0 \) and \( LB(h^*_{j,l}) = h^*_{j,l} \). With respect to the bus voltage magnitude, since \( \hat{h}^*_{j,l} > h^*_{j,l} > h^*_{j,l} > \hat{h}^*_{j,l} \), the initial values of these four bounds can be set to \( UB(\hat{h}^*_{j,l}) = \hat{h}^*_{j,l}, LB(\hat{h}^*_{j,l}) = \hat{h}^*_{j,l} + d, UB(h^*_{j,l}) = \hat{h}^*_{j,l} + d \) and \( LB(h^*_{j,l}) = h^*_{j,l} \), where \( d \) is a positive real number.

- **Algorithm**

Based on the analysis presented in Sections 2.2.1 and 2.2.2, the algorithmic steps of the proposed RSONP algorithm for solving the RSONP problem (Equation (2)) can be presented in the following.

**Given data:** The pdf \( p(v_l) \), parameters \( C_p, a, A \) and \( |\cos \phi_{D_l}| \) of bus \( l \) in WG. The pdf \( p(P_{D_l}) \) and \( |\cos \phi_{D_l}|, \forall i = 1, \cdots, N_l \). The \( m \) ANNs constructed off-line. The values of \( \eta, d \) and \( \varepsilon \).

**Step 0:** Calculate \( \hat{u}_{W_l} = [\hat{h}_{W_l}, \hat{Q}_{W_l}]^T \) using Equations (4) and (5) and calculate \( \hat{u}_{D_l} = [\hat{h}_{D_l}, \hat{Q}_{D_l}]^T \) using Equation (6) based on \( p(v_l) \) and \( p(P_{D_l}) \). For \( j = 1, \cdots, m \), set initial values of \( UB(\hat{h}^*_{j,l}), LB(\hat{h}^*_{j,l}), UB(h^*_{j,l}) \) and \( LB(h^*_{j,l}) \) as described above, and calculate \( \hat{h}_{j,l} \) and \( h^*_{j,l} \) by Equations (15) and (16).
Step 1: Solve OPFPRB (Equation (3)) using an available OPF solution method [30] and obtain the SONP $u_{iG}^{*}$, $i \in G \setminus WG$.

Step 2: Use $2K + 1$ point estimation method to estimate $\mu_h$ and $\sigma_h$ of $h_j(\tilde{x})$ for $j = 1, \ldots, m$.

Step 3: For $j = 1, \ldots, m$, input $\mu_h$ and $\sigma_h$ obtained in Step 2, into the jth ANN, and whose outputs are the estimated $\eta$-upper bound $\eta y_j(h^*, \tilde{h}^*)$ and $\eta$-lower bound $\eta y_j(h^*, \tilde{h}^*)$ of $h_j(\tilde{x})$.

Step 4: For $j = 1, \ldots, m$, update $UB(h^*_j)$, $LB(h^*_j)$, $UB(h^{**}_j)$ and $LB(h^{**}_j)$ using Equations (17)–(20), and update $h^*_j$ and $h^{**}_j$ using Equations (15) and (16).

Step 5: If both $UB(h^*_j) - LB(h^*_j) < \epsilon h^*_j$ and $UB(h^{**}_j) - LB(h^{**}_j) < \epsilon h^*_j$ hold for all $j = 1, \ldots, m$, stop and the final $LB(h^*_j)$ and $UB(h^{**}_j)$ are the solutions for $h^*_j$ and $h^{**}_j$, respectively, for $j = 1, \ldots, m$; otherwise, return to Step 1. If the algorithm stops, output the optimal restrictive bounds $(h^*_i, h^{**}_i)$ and the OSONP $u_{iG}^{*}$, $i \in G \setminus WG$, which is obtained from Step 1 in the final iteration.

2.2.4. Flow Chart of the Risk-Limiting Schedule of Optimal Non-Renewable Power-Generation Algorithm

The structure of the proposed RSONP algorithm for solving the RSONP problem can be summarized by the flow chart presented in Figure 2, and the corresponding algorithmic steps are also indicated in the figure.

![Figure 2](image-url)

**Figure 2.** Flow chart of the risk-limiting schedule of optimal non-renewable power-generation algorithm.
3. Results and Discussion

3.1. Setup of Tests

The IEEE 118-bus system that is presented in [31] is used as the test system. In this system, there are 44 non-renewable power generation buses, 10 wind power generation buses and 25 buses of large load demand. Consequently, \(|WG| = 10, N^L = 25\) and \(K = 35\). Bus 69 is designated as the swing bus; the number of transmission lines is 186, so \(m = 304\). \((\mathbf{V}_p^0, \mathbf{V}_q^0)\) and \((\mathbf{p}_i^0, \mathbf{q}_i^0)\) are set to (0.95, 1.05) and \((-|p_{ij}|(1 + 7\%), |p_{ij}|(1 + 7\%))\), respectively, where \(|p_{ij}|\) is the absolute value of the \(p_{ij}\) in the base case. In the OPFPRB (Equation (3)) and COPF problem (Equation (1)), the values of the cost coefficients \(a_i, b_i\) and \(c_i\) \(\forall i \in G \setminus WG\) are randomly selected from the intervals (6.78, 74.33), (8.3391, 37.6968) and (0.002401, 0.069663), respectively. Notably, the units of Table 1 are reported or evaluated in this test.

</tr>
</tbody>
</table>

The Terms (a) and (b) correspond to the run time of the RSONP algorithm. Term (c) is the optimal objective value of the RSONP problem (Equation (2)). Term (d) represents the scheduled optimal total non-renewable power generation cost in unit \$/h, which is the optimal objective value of the OPFPRB (Equation (3)) when \((\mathbf{h}^s, \mathbf{h}^Q) = (\mathbf{h}^{s*}, \mathbf{h}^{Q*})\). Term (e) reflects the performance of the...
OSONP \( u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), and is evaluated based on the MCS presented in Section 2.1.3 but replacing \((\hat{h}^i, \hat{R}^i)\) and \(u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG\) by \((h^i, R^i)\) and \(u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG\), respectively.

Table 2 presents the test results concerning the aforementioned five terms that were obtained using the proposed RSONP algorithm in Case A. Although RSONP algorithm takes ten iterations to reach the termination criterion, the results that were obtained in 6–9 th iterations are also reported. Columns 1 and 3 of Table 2 reveal the iteration-wise improvement of the objective value of the RSONP problem (Equation (2)), indicating that the distance between the obtained restrictive bounds and the normal bounds becomes smaller each iteration. As the restrictive bounds become less restrictive, the scheduled optimal total non-renewable power generation cost shown in Column 4 of Table 2 becomes smaller as predicted. Moreover, as the restrictive bounds becomes more restrictive, the performance of the OSONP \( u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), improves but at the cost of an increase in the scheduled optimal total non-renewable power generation cost as is observed from Columns 3–5 in Table 2. This is reasonable, because a higher cost is required for a better performance. The performance of the OSONP \( u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), in iterations six to ten of the RSONP algorithm exceeds 0.95 and the consumed CPU time are all less than 83.4 s, as revealed by Columns 5 and 2 in Table 2. In fact, the RSONP algorithm can be terminated after iteration 7, because the corresponding CPU time is less than one minute, but the performance is 0.55% better than that achieved in ten iterations, at the cost of only a 0.03% increase in the scheduled optimal total non-renewable power generation cost. The above results imply the following. The solution obtained at the end of iteration ten being the best is simply because the objective function of the RSONP problem (Equation (2)) considers only Term (c) that is proportional to Term (d), the non-renewable power generation cost, but do not consider Term (e), the performance regarding the probability of satisfying the security constraints in the presence of uncertain power generation and load demand. Since some system operators may care more about the security than the cost, a multi-objective OPF that considers both non-renewable power generation cost and the probability of satisfying the security constraints would be an issue that is worthy of investigation.

* Terms regarding (a)-(e) are specified in Table 1.

To demonstrate the advantage of the RSONP algorithm, the performance of the obtained OSONP \( u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), is compared with the conventional schedule of optimal non-renewable power-generation (CSONP) \( u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), which is obtained by solving the COPF problem (Equation (1)) using the OPF solution method [30] that was used in Step 1 of the RSONP algorithm. The performance of \( u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), is defined as Prob\{\(|h_j^i| \leq h_j(\tilde{x}^i)\) \leq R_j^i, \forall j = 1, \cdots, m|h^o, R^i), where \(\tilde{x}^i\) is the normal-bound-based random state-vector after re-dispatching (NRSAR) for all buses \(i = 1, \cdots, N\). The NRSAR \(\tilde{x}^i\) is obtained using the procedure that was elucidated in the re-dispatching stage (Section 2.1.3) but with \(u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), and \(\tilde{x}^i\) replaced by \(u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), and \(\tilde{x}^i\), respectively, where \(\tilde{x}^i, \forall i \in G \setminus WG \), is the Normal-bound-based Non-renewable Power-generation After Re-dispatching (NNPAR) that was obtained by re-dispatching the CSONP \( u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), using Equations (9) and (10) based on the re-dispatching percentage share in Case A. The procedure for evaluating Prob\{\(|h_j^i| \leq h_j(\tilde{x}^i)\) \leq R_j^i, \forall j = 1, \cdots, m|h^o, R^i\} in Case A is also based on the MCS presented in Section 2.1.3 but replacing \((h^i, R^i)\) and \(u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \) by \((h^o, R^o)\) and \(u_{G_i}^{\epsilon*}, \forall i \in G \setminus WG \), respectively.

* Terms regarding (a)–(e) are specified in Table 1.

To demonstrate the advantage of the RSONP algorithm in Case B, the performance of the previously obtained CSONP \( u^{\text{CSONP}}_{G,i}, \forall i \in G\setminus WG \), is also investigated in Case B. The test procedures are the same as that for Case A described in Section 3.2 except for the re-dispatching percentage share. The test result shows that the performance of the CSONP \( u^{\text{CSONP}}_{G,i}, \forall i \in G\setminus WG \), i.e., \( \text{Prob}\{h^{\circ} \leq h, \tilde{x}^{\circ} \leq \tilde{h}, \forall j = 1, \cdots, m|\tilde{x}^{\circ}, \tilde{h}^{\circ}\} \) in Case B is 0.7715 (<0.95) in contrast to the larger than 0.95 performances resulted from all the OSOPN \( u^{\text{OSOPN}}_{G,i}, \forall i \in G\setminus WG \), obtained by executing the RSONP algorithm using 6 to 10 iterations as presented in Table 3. Notably, the total non-renewable power generation cost of CSONP \( u^{\text{CSONP}}_{G,i}, \forall i \in G\setminus WG \), in Case B is exactly the same as that presented in Case A. Therefore, comparing with the CSONP \( u^{\text{CSONP}}_{G,i}, \forall i \in G\setminus WG \), the performance of the OSOPN \( u^{\text{OSOPN}}_{G,i}, \forall i \in G\setminus WG \), obtained from executing the RSONP algorithm for 10 iterations in Case B is 23.35% better at the small cost of a 0.022% increase in the total non-renewable power generation cost. Since the re-dispatching percentage share for all the non-renewable power generation busses in these two cases are extremely different, the test results presented in Tables 2 and 3 demonstrate the robustness of the proposed RSONP algorithm.

4. Conclusions and Further Research

Intermittent renewable power generation and uncertain load demand may cause security constraints to be violated. To limit this risk, an RSONP problem is formulated and a computationally efficient RSONP algorithm is presented and tested on the IEEE 118-bus power system. The computing speed of the RSONP algorithm and its comparison with the CSONP show that it can be applied in real time to reduce the risk of violating security constraints at the very small cost of an increase in
the total non-renewable power generation cost. As for further research, due to the conflicting nature between the non-renewable power generation cost and the probability of satisfying security constraints indicated in Section 3.2, it would be worthwhile to formulate a multi-objective OPF problem by taking into account the aforementioned two conflicting terms and propose a computationally efficient algorithm to solve it.

Acknowledgments: This research work is supported in part by the Ministry of Science and Technology in Taiwan under grant MOST 105-2221-E-182-038. Ted Knoy is appreciated for his editorial assistance.

Author Contributions: Shin-Yeu Lin proposed the idea of this research and wrote the paper. Ai-Chih Lin designed and performed all the computer programs and simulations.

Conflicts of Interest: The authors declare no conflict of interest.

Nomenclature

- **OPF**: Optimal power flow
- **RSONP**: Risk-limiting schedule of optimal non-renewable power-generation
- **MCS**: Monte Carlo simulation
- **OPFPRB**: OPF problem with restrictive bounds, Equation (3)
- **SONP**: Scheduled Optimal Non-renewable Power-generation
- **COPF**: Conventional OPF
- **SONOP**: Non-renewable Power-generation After Re-dispatching
- **RSAR**: Random State-vector After Re-dispatching
- **STAR**: Security Term after Re-dispatching
- **CSONP**: Conventional Schedule of Optimal Non-renewable Power-generation
- **NNPAR**: Normal-bound-based Non-renewable Power-generation after Re-dispatching
- **V_{i}/\theta_{i}**: Voltage magnitude/phase angle of bus $i$
- **$x_{i} = [V_{i}, \theta_{i}]^{T}$**: State variable of bus $i$
- **N/L**: Total number of busses/the set of all transmission lines of the system
- **$x = [x_{1}^{T}, \cdots, x_{N}^{T}]^{T}$**: State vector of all busses
- **$G_{WG}/G_{\text{WG}}$**: Set of all/wind power/non-renewable power generation busses
- **$P_{G_{i}}/Q_{G_{i}}$**: Real/reactive power generation at bus $i$
- **$u_{G_{i}} = [P_{G_{i}}, Q_{G_{i}}]^{T}$**: Power generation at bus $i$
- **$\bar{u}_{G_{i}}, \underline{u}_{G_{i}}$**: Upper/lower bound of $u_{G_{i}}$
- **$v_l, l \in WG$**: Random wind speed of wind power generation bus $l \in WG$
- **$p(v_l)$**: Probability density function (pdf) of random wind speed $v_l$
- **$\hat{u}_{W_{l}}$**: Predicted wind power generation at bus $l$
- **$\hat{u}_{W_{l}}(v_l)$**: Random wind power generation at bus $l$
- **$\hat{u}_{D_{L}}$**: Vector of predicted large load-demand
- **$\hat{u}_{D_{S}}$**: Vector of predicted small load-demand
- **$\hat{u}_{D} = [\hat{u}_{D_{L}}^{T}, \hat{u}_{D_{S}}^{T}]^{T}$**: Random large load demand at bus $D_{i}^{L}$
- **$\tilde{u}_{D_{L}} = [\tilde{u}_{D_{L}}^{(1)}, \cdots, \tilde{u}_{D_{L}}^{(N_{L})}]^{T}$**: Random vector of large load demand
- **$p(\tilde{u}_{D_{L}})$**: Probability density function (pdf) of random large real load demand at bus $D_{i}^{L}$
- **$p_{ij}$**: Real power flow over transmission line $(i, j)$
\[ P_{ij}^u / P_{ij}^l \]
\[ g(x, u_G, u_W, u_D) = 0 \]
\[ \sum_{i \in G \setminus WG} a_i P_{G_i}^2 + b_i P_{G_i} + c_i \]
\[ h_j \]
\[ \tilde{h}_j^u / \tilde{h}_j^l \]
\[ \eta \]
\[ \eta / \eta \]
\[ \eta \]
\[ r_{P\%} / r_{Q\%} \]
\[ u_G, \forall i \in G \setminus WG \]
\[ u_{G\%}^*, \forall i \in G \setminus WG \]
\[ u_{G\%} \]
\[ u_{G\%} \]
\[ NRSAR \]
