Abstract: Methane is the fundamental raw material of the C1 chemical industry, with abundant reserves. Its direct conversion into high-value-added chemicals has great scientific significance and broad commercial potential for the efficient use of methane resources. However, it is difficult to convert methane into more useful hydrocarbons and hydrogen, as the reaction usually requires external energy to overcome thermodynamic limitations. Non-oxidative coupling of methane to produce ethane and hydrogen is a promising supply technology. Catalysts which can be adapted to various energy sources are key to this technology. In recent years, considerable progress has been made in the design and application of these thermal and photocatalysts. This review outlines some typical catalysts, and reviews the progress in the understanding of reaction mechanisms. Finally, suggestions for the development of high-selectivity and high-stability catalysts for the future are presented.

Keywords: photocatalysis; thermal catalysis; non-oxidative coupling of methane; ethane; hydrogen

1. Introduction

With the global temperature rising each year, climate anomalies are becoming more and more frequent, greatly impacting the bulk commodity market, especially in energy. Consequently, the utilization of clean energy natural gas is rapidly expanding with the exploitation of shale gas and combustible ice [1]. In the past, natural gas was mainly used as fuel [2], but now, in order to achieve green and sustainable development of the energy system, its industrial utilization is gaining more attention [3].

Natural gas is mainly composed of methane (CH₄)-the basic raw gas of the C1 chemical industry. Thus, the conversion of CH₄ to high-value chemicals (such as hydrogen (H₂), alcohols, alkanes, and olefins) is a promising technology in chemical and energy supply. Traditionally, these chemicals are obtained through the indirect conversion of CH₄, that is, CH₄ is first converted into syngas (CO and H₂), and then processed through the Fischer–Tropsch process. Unfortunately, this method has some disadvantages, such as a complicated process, low utilization rate of CH₄, high energy consumption, and high cost [4,5].

The industry has been seeking cost-effective and low-carbon ways to utilize CH_4 , of which ethene (C_2H_6) is a highly important commodity chemical for many manufacturing products [6]. Non-oxidative coupling of methane (NOCM) produces C_2H_6 and H_2 (Equation (1)), making it the simplest C-C coupling process and a model reaction for converting CH_4 to multi-carbons.

$$2CH_4 \to C_2H_6 + H_2 \Delta H (298K) = 68.6 \text{ kJ mol}^{-1}$$
(1)

However, the thermodynamic barrier of this reaction necessitates the use of energy sources to trigger CH₄ coupling [2,7], such as thermal catalysis and photocatalysis. Thermal

catalysis is the most common method, but carbon deposition occurs easily at relatively high temperatures (>773 K) [8] and complete dehydrogenation of CH_4 reduces C_2H_6 selectivity. Solar energy, on the other hand, is the richest and cleanest renewable energy and has been used to promote NOCM reactions under mild conditions [9,10], improving system safety and reducing reaction temperature.

From an economic standpoint, Gerceker et al. suggested that the selectivity of C_2H_6 should be at least 25% and coke formation should be less than 20%, making it a viable option for commercial applications [11]. Additionally, CH₄ conversion efficiency should be taken into consideration. To this end, this paper reviews a series of catalysts from the perspective of catalytic efficiency and the mechanism of typical thermal catalysis and photocatalysis in NOCM reactions. In thermal catalysis, the catalysts reduce the reaction barrier and regulate the reaction intermediates in the "adsorption-activation-desorption" process. For photocatalysis, catalysts with different electronic properties are excited by solar energy to regulate the C-C coupling process. An overview of the properties and mechanism of the active catalysts is provided, as well as factors that affect CH₄ activation and C_2H_6 selectivity. Designing efficient catalysts for direct NOCM is of great importance for the future.

2. Thermal Catalytic NOCM

2.1. Fundamentals of Thermal Catalysis

Generally, it is assumed that the reaction of Thermal Catalytic NOCM consists mainly of three processes [12]: (1) CH₄ is adsorbed onto the active site of the catalyst; (2) the C-H bond is dissociated by the active component and forms adsorbed methyl or H₂; (3) the identical adsorbed groups are coupled, then desorbed to generate C₂H₆ and H₂ in the gas phase. However, as the most stable alkane, the CH₄ molecule is sp^3 hybrid [13] and its C-H bond dissociation energy is up to 439 kJ mol⁻¹ [14,15], making the activation energy of the reaction extremely high, despite the catalyst reducing the energy effectively. The first C-H bond breaking of CH₄ is more difficult, whereas the successive dehydrogenation reaction is easy to occur, thus leading to methyl cracking without needing a coupling process.

In thermal catalytic NOCM, the C-H bond of the CH₄ molecule is broken through high-temperature thermal energy. The generation of reaction intermediates is regulated by introducing a thermal catalyst, thus avoiding the fracture of the CH₃-CH₃ skeleton, and effectively improving the catalytic performance. Some typical thermal catalysts are summarized in Table 1.

Entry	Catalysts	Temperature (K)	Reaction Conditions	C ₂ H ₆ Selectivity (%)	CH ₄ Conversion (%)	Reference
1	Pt	523	$100 \text{ mg}, 400 \text{ mL min}^{-1} \text{ CH}_4$	-	19.3	[16]

2.2. Precious Metal Catalysts

Noble metal catalysts can more effectively control the adsorption and desorption of intermediate products in thermal catalytic NOCM, thus enabling the directional conversion of CH₄ to C_2H_6 [19]. In 1991, Belgued et al. [17] explored the effect of temperature on the selectivity of C_2H_6 over Pt/CeO₂ catalyst (Figure 1a,b). With increasing temperature, the adsorption of methyl (-CH₃) on the Pt surface decreased, whereas the formation of

intermediates such as -CH₂, -C₂H₃, and -C₂H₂ accelerated, thus reducing the selectivity of C₂H₆. Moya et al. [18] confirmed that the highly dispersed Pd active sites chemisorbed intermediate carbon species, promoting the desorption balance of methyl (-CH₃) and proton hydrogen (H) over a Pd/ α -Al₂O₃ catalyst during the coupled hydrogenolysis of CH₄ at low temperature (500–750 K) (Figure 1c). Thermodynamic constraints in the thermal catalytic reaction motivate research into CH_4 activation at high temperatures. However, traditional metal cluster catalysts suffer from severe coking and significant deactivation in the hightemperature catalytic process. Xie et al. [21] used a single atom Pt₁@CeO₂ catalyst to achieve a 40 h catalytic cycle (1173 K). The continuous desorption of intermediates (-CH₃ and -CH₂) at atomically dispersed Pt sites improves the effective collision of carbon-containing intermediates on the surface of active sites and inhibits carbon deposition, which covers the active sites, thereby aiding the dynamic stability of the catalyst structure. In conclusion, it can be stated that precious metal catalysts can facilitate the adsorption energy of -CH₃ on the catalyst surface under appropriate catalytic temperature conditions, while inhibiting the adsorption of H atoms by unsaturated coordination carbon-containing intermediates, thus enhancing the effective collision between adsorbed CH₃, and consequently promoting the coupling stability of C_2H_6 . Recently, Pt nanolayers anchored at the hexagonal close-packed sites of the MXene support were able to activate the primary C-H bond of CH₄ to create methyl radicals that favor desorption over subsequent dehydrogenation, suppressing coke deposition. At 973 K, the catalyst could operate continuously for 72 h without deactivation and CH_4 conversion reached 7% (Figure 1d,e) [19].

2.3. Non-Precious Metal Catalysts

Compared with expensive precious metals, relatively cheaper non-precious metal catalysts such as Fe have been found to successfully catalyze the direct dehydrogenation of CH₄ to generate carbonaceous metal compounds (MeC_x) [13,27], resulting in improved stability of the catalyst even under high-temperature conditions. In 2014, Bao et al. [20] used an Fe©SiO₂ catalyst to achieve catalytic stability for 60 h continuously, with a selectivity of C₂H₆ of around 3% at 1223 K (Figure 2a,b). FeO_x is confined in the SiO₂ lattice, with -CH₃ species released from the constrained Fe atom. After CH₄ is completely dehydrogenated, the carbon species are directly converted into a FeC_x solid solution from the C-Fe=CH₂ structure, avoiding carbon deposition. Kim et al. [22] found that the concentration of -CH₃ species affects the catalytic process, with a high concentration of -CH₃ (log_{PCH3} > -2) atmosphere being conducive to the formation of C₂H₆. Conversely, low concentrations of

 CH_3 (log_{PCH3} < -3) conditions result in C_2H_6 continuing to dehydrogenate as a medium for the formation of C_2H_4 or C_2H_2 (Figure 2c). It was shown that by regulating the formation energy of -CH₃ species over Fe©CRS (CRS:SiO₂) catalyst at 1353 K, catalytic stability could be achieved for 50 h, with a selectivity of C_2H_6 maintained at 7.9%. Mechanism studies confirmed that the energy barrier to be overcome for complete CH₄ cracking on the confined Fe₃C surface ($\Delta G = 1.1 \text{ eV}$) is lower than that of the pure Fe₃C surface $(\Delta G = 2.8 \text{ eV})$ (Figure 2d), with the formation energy of -CH₃ species on the restricted Fe_3C surface site being lower than that of the pure Fe_3C site (Figure 2d). Li et al. [28] proposed a quasi "Mars-van Krevelen" surface reaction mechanism, and research showed that the extraction and refilling of surface carbon atoms was the key to the transformation of surface carbon species. The -CH₃ species on the surface of Fe₁©SiO₂ catalyst are difficult to desorb into the gas phase at the single iron atom site, whereas the carbon sites adjacent to the iron atom are more likely to desorb $-CH_3$ and transfer protons H, thereby promoting the cyclic conversion of carbon atoms on the surface. Kashaboina et al. [29] confirmed that the in situ transformation of the unsaturated coordination structure of the In-C bond is a necessary condition for the formation of C_2H_6 on In/SiO₂ catalyst by in situ X-ray absorption spectroscopy. Moya and Rashid et al. [26,30] proved that Ni²⁺ is conducive to CH_4 adsorption, with the CH_4 adsorption capacity of the catalyst containing Ni^{2+} being 13 times that of the catalyst containing Ni^0 . Dipu et al. [23] found that the selectivity of C_2H_6 can reach 80% on the variable valence metal Ni-P/SiO₂ catalyst at 1098 K (Figure 2e). Lin et al. [31] showed that the divalent metal Ta^{2+} site is the active center on the Ta/SiO_2 catalyst, with the Si-O-Ta bond in (-SiO₃)₂Ta being broken and the H₂-Ta-CH₂CH₃ structure formed during activation of CH_4 , which can then be dehydrogenated to Ta-H and C_2H_6 . Soulivong et al. [25] achieved a selectivity of the products of around 50%, with catalytic stability maintained for 200 h over Ta/SiO₂ catalyst at 573 K. Therefore, non-precious metal catalysts can promote the C-C coupling of CH₄ through a "restriction strategy" or "metal valency change strategy" to obtain the target products of C₂H₆ and H₂.

3. Photocatalytic NOCM

3.1. Fundamentals of Photocatalysis

In the photocatalytic NOCM process involving a semiconductor catalyst, solar energy is utilized to stimulate the catalyst, creating photogenerated carriers (electrons and holes) [15]. The generated holes at the valence band trigger CH₄ to enter an excited state, forming methyl radicals (•CH₃) and H protons (CH₄ + h⁺ \rightarrow •CH₃ + H⁺). Subsequently, methyl radicals are combined to yield adsorbed C₂H₆ (2•CH₃ \rightarrow C₂H₆), whereas the protons H are reduced by electrons to give adsorbed H₂ (2H⁺ + 2e⁻ \rightarrow H₂) [32]. Finally, C₂H₆ and H₂ are desorbed in the CH₄ conversion process at low temperatures [33].

Moreover, several catalysts with no inherent semiconductor characteristics are also applied for photocatalytic NOCM, which are distinguished by dispersing highly active centers on non-photoresponsive insulator supports and localizing on specific sites by taking advantage of the interaction between active components and supports. Some typical photocatalysts that can improve CH_4 conversion or C_2H_6 selectivity are summarized in Table 2.

Table 2. C₂H₆ selectivity and CH₄ conversion in photocatalytic NOCM using different catalysts.

	Catalysts	Reaction Conditions	C_2H_6 Selectivity (% or μ mol g ⁻¹ h ⁻¹)	CH ₄ Conversion (% or μ mol g ⁻¹ h ⁻¹)	Reference

3.2. Metal-Oxide-Based Catalysts

In 1998, Yoshida et al. [34] first reported that a SiO₂-Al₂O₃ catalyst could be utilized for NOCM, but its C₂H₆ selectivity was limited to 0.01%. Subsequently, Yoshida et al. found that high-energy ultraviolet light could induce the CH₄ molecule to transition directly from its ground state to an excited state, and the phosphorescent excitation sites of SiO₂ could desorb hydroxyl (-OH) groups from the surface [49]. Yuliati also confirmed that the dehydroxylation of SiO₂ could be achieved by two active sites, namely, the \equiv Si–O• (NBOHC, non-bridging oxygen hole center) and the •Si \equiv (E' center, dioxasilirane group), with electrons being obtained at the NBOHC site and holes generated at the E' center site [35].

To further increase the light absorption capacity of the catalyst, some researchers have introduced the highly dispersed photoactive component TiO₂. In 2002, Yoshida et al. [37,38] reported that a ternary oxide catalyst of SiO₂-Al₂O₃-TiO₂ achieved a C₂H₆ selectivity of 2.07%. The mechanism study showed that CH₄ was activated by ultraviolet light, and its surface hydroxyl groups desorbed to form (SiO)₃Ti-O-Al(OSi)₃, which acted as a highly active synergistic site to promote the electron transfer from the

oxygen center to the titanium site [38]. In 2021, Zhang et al. [39] proposed an efficient "coupling-desorption mechanism" strategy to regulate the yield of C_2H_6 , with the yield of C_2H_6 reaching 1.7 µmol g⁻¹ h⁻¹ over the *n*-type semiconductor Nb-TS (single atom Nb-doped TiO₂-SiO₂) catalyst (Figure 3). Nb doping replaced the six coordinated Ti6c sites, generating additional active sites to provide additional local electrons which facilitated the directional migration of electrons to local •CH₃, thereby accelerating the coupling between CH₃-CH₃ species and desorbing more C_2H_6 .

Figure 3. The hydrocarbon products, H₂ yields, and the CH₄ conversion rate over Nb-T [39]. Copyright 2021, John Wiley and Sons.

Based on the above research, it can be determined that in the photocatalytic NOCM process, metal oxide catalysts mainly utilize high-energy ultraviolet light to induce CH₄ to directly transition from the ground state to the excited state, and then adjust the surface electron transfer process through the oxide surface adsorption characteristics, thus improving CH₄ conversion and C₂H₆ selectivity by promoting the formation of adsorbed protons (H) and adsorbed •CH₃.

3.3. Metal-Modified Catalysts

The semiconductor catalyst has fixed intrinsic characteristics, making it difficult to meet the needs of photocatalytic reactions. Therefore, it is necessary to adjust the electronic structure of the catalyst by modifying the cocatalyst to optimize its catalytic performance. One strategy is to use metal-modified catalysts to broaden the light response region and improve the conversion efficiency of solar energy. Moreover, metal-modified photocatalysts can generate hot electrons or local electric fields to activate the C-H bond of CH₄, promoting the reaction [50]. The metal can also undergo a change from Me^{1+x} to Me^x during the reaction, which regulates the adsorption-desorption reaction involving CH₄ [50,51].

Yoshida et al. [42,43] found that adjusting the metal loading could achieve metal valence state modulation, thereby modifying the selectivity of C_2H_6 . Ce³⁺ promotes fast electron migration in the low-loaded $Ce_{(0.01-0.1\%)}/SiO_2$ catalyst, resulting in C_2H_6 selectivity of up to 60%. However, a higher loading of $Ce(2-5\%)/SiO_2$ catalyst yields a selectivity of 99% due to Ce⁴⁺ widening the band gap and inhibiting CH₃ dehydrogenation. Later, Yoshida et al. [40] proposed the "Ag⁺-Ag⁰-Ag⁺ cycle balance charge" mechanism, and a C₂H₆ selectivity of 4.40% was achieved over Ag-MFI (MFI: SiO₂-A1₂O₃) catalyst. The photoexcited Ag⁺ adsorbs CH_4 to form a complex (ZO-(Ag⁺-CH₄), which promotes the adsorption of CH₄. During the conversion of Ag⁺ to Ag⁰, the C-H bond is broken and •CH₃ species accumulate on the catalyst surface, increasing the C-C collision opportunity to form C_2H_6 . In 2020, Yu et al. [2] confirmed the reversibility of "Ag⁺-Ag⁰-Ag⁺" over the Ag-HPW/TiO₂ catalyst. The yield of C_2H_6 was found to reach 150 µmol g⁻¹ h⁻¹, and the optical quantum efficiency was 3.5% (362 nm). It was further demonstrated that during the photocatalytic CH₄ coupling reaction, the Lewis acid sites around the low coordination Ag⁺ are converted into Brønsted acid, and the Ag⁰ formed in situ is the active center site for the generation of \bullet CH₃ (Figure 4a,b).

(f) CH₄ conversion and C₂H₆ selectivity of Zn²⁺-ZSM-5⁻ catalyst [44], and (g) mechanism of Zn²⁺-ZSM-5⁻ catalyst in photocatalytic NOCM [44]. Copyright 2011, John Wiley and Sons.

Li et al. [41] replaced Ga cations on the titanate framework (ETS-10, one-dimensional TiO₂ nanowires surrounding SiO₂) to obtain C₂H₆ selectivity of up to 70%. The study showed that CH₄ is adsorbed on the Ga site and the holes are captured by the -OH group. Then, hydroxyl radical (•OH) forms by attacking the C-H bond to generate •CH₃. Subsequently, the same kind of groups of •CH₃ are coupled to form C₂H₆(Figure 4d). At the same time, Ti⁴⁺ captures electrons to form Ti³⁺, and Ti³⁺ further transfers its electrons to the lattice oxygen to form the interaction between superoxide radicals (O²⁻) and H₂O (Figure 4c,d). Later, Li et al. [44] designed an electron delocalization state in the Zn²⁺⁻ZSM-5⁻ catalyst, achieving a selectivity of C₂H₆ close to 100%. UV light-excited free electrons transform to the 4s orbital of Zn²⁺ to form Zn⁺. Zn⁺ attracts the H atom of the CH₄ molecule, then the anti-bond orbital obtains the 4s orbital electrons of Zn⁺. This facilitates the desorption of a large number of protons and induces C-C coupling to form C₂H₆ (Figure 4f–g).

Ga₂O₃ with a wide band gap can withstand a strong electric field to polarize CH₄ molecules, and its cluster center bridges oxygen center radicals to promote the decomposition of CH₄ molecules under mild conditions [52]. In 2008, Yuliati et al. [45] achieved a selectivity of 94% for C₂H₆ on Ga_(0.1)/SiO₂ catalyst. The tetrahedral coordinated Ga₂O₃ active site selectively activated CH₄ molecules by limiting electrons in the Si-O bond through the Si-O-Ga structure. This is distinct from the electron transfer from O²⁻ to Ga³⁺ during photoexcitation, which is more conducive to the selective generation of C₂H₆. Moreover, Pratap Singh et al. [32] found in 2020 that increasing light intensity can not only promote the activation of the C-H bond but also accelerate the photooxidation reaction of •CH₃ (•CH₃ + 3h⁺ \rightarrow C + 3H⁺)(Figure 5a), which is not beneficial for forming C₂H₆.

Figure 5. (a) Production rates on Pd/Ga_2O_3 with different light intensities [32], copyright 2011, Elsevier. (c) C_2H_6 yield over TiO₂ catalysts supported by different noble metals in NOCM [53], and (d) IR spectra over Au/TiO₂ and P25 [53]. Copyright 2020, Royal Society of Chemistry.

Zhang et al. [46] studied the influence of the size effect of the active metal Pt. The catalytic activity showed a volcanic trend when the crystal size of Pt increased from 1.5 nm to 2.7 nm, and the maximum selectivity of C_2H_6 reached 90%. Small grain size is favorable for $Pt^{\delta+}$ transfer of photogenerated holes from Ga_2O_3 to adsorbed CH_4 molecules. Though the selectivity of C_2H_6 on metal-modified Ga_2O_3 is not low, its CH_4 conversion is not high (Figure 5b). Wu et al. [48] reported that Ga doping increased the free electron concentration on the Pt site. More Pt⁰ can effectively dissociate the C-H bond. Furthermore, the Mott– Schottky heterojunction formed at Pt-TiO₂ accelerates the separation of the photogenerated carrier. Thus, the selectivity of C_2H_6 is 90% and the conversion of CH_4 is 28% on the *n*-type semiconductor Pt/HGTS catalyst (HGTS: Ga doped TiO₂-SiO₂). Lang et al. [53] found that the lower the interface potential of metal modification, the more difficult the recombination of photogenerated carriers, which is more conducive to enhancing catalytic performance. By comparing a series of TiO_2 (P25) catalysts modified by precious metals (Ru, Rh, Pd, Ag, Ir, Pt, and Au), it was found that the interface potential on Au-TiO₂ is the lowest, which is more conducive to rapid electron migration to activate CH₄ molecules. Consequently, the yield of C₂H₆ can reach 81.7 μ mol g⁻¹ h⁻¹ on the Au-TiO₂ catalyst (Figure 5c,d).

Generally, photogenerated holes used to activate CH_4 are mainly concentrated at the lattice oxygen sites of metal oxide semiconductors, which makes CH_4 prone to overoxidation by lattice oxygen atoms to produce CO, CO_2 , and other by-products. Xiong et al. [54] proposed the single-atom coordination method to regulate the valence band electronic structure of the Pd/TiO₂ catalyst. This resulted in a selectivity of up to 94.3% for C_2H_6 , a C_2H_6 yield of 0.91 mmol g⁻¹ h⁻¹, and H₂ products with an equal stoichiometric ratio (Figure 6). Photogenerated holes were clustered on the "Pd-O₄" coordination structure, thus reducing the contribution of the oxygen site to the valence band and improving the stability of lattice oxygen. This was shown to improve photocatalytic performance and reduce excessive oxidation in NOCM.

Figure 6. The comparison of production rate between Pd₁/TiO₂ and Pd₁/ST [54]. Copyright 2022, Springer Nature.

In addition, some other studies have found that an increase in CH_4 pressure in the reaction system (from 0.27 kPa to 0.49 KPa) can reduce the catalytic activity [36]. Furthermore, the type of light source, light intensity, the reaction device, temperature, and pressure of the reaction system are all important factors affecting the anaerobic coupling of photocatalytic CH_4 .

4. Conclusions and Outlook

Direct conversion of CH_4 to C_2H_6 and H_2 has gained much attention due to its low cost, low carbonization, and other benefits. This review seeks to systematically analyze the development of thermal and photocatalytic NOCM, including the study of material properties and the exploration of reaction mechanisms. In contrast to other CH_4 conversions, non-oxidative coupling of CH_4 generates many by-products.

In traditional thermal catalytic NOCM, the C-H bond of CH₄ is broken through the application of high-temperature thermal energy. The range of 1053–1123 K is more conducive to the selective generation of C_2H_6 , since it is an optimal balance between breaking the C-H bond and the CH₃-CH₃ coupling progress. However, with increasing temperature, the adsorption of methyl (-CH₃) on the precious metal catalysts surface weakens and the formation of intermediates such as -CH₂, -C₂H₃, and -C₂H₂ accelerates, thereby reducing the selectivity of C₂H₆. Non-precious metal catalysts, on the other hand, can promote the C-C coupling of CH₄ through the "restriction strategy" or "metal price change strategy" to obtain the target products of C₂H₆ and H₂.

Photochemical reactions driving NOCM can break the restriction of thermodynamic equilibrium at mild temperatures. Metal-oxide-based catalysts which do not have the inherent characteristics of semiconductors can be applied for photocatalytic NOCM, whereby CH₄ is directly converted from the ground state to the excited state under solar energy, thereby promoting the formation of adsorbed protons (H) and adsorbed •CH₃. This is achieved by dispersing highly active centers on non-photoresponsive insulator supports and localizing them on specific sites through the interaction between active components and supports. Additionally, it is useful for metal-modified catalysts to broaden the light response region and improve the conversion efficiency of solar energy. This can generate hot electrons or local electric fields to activate the C-H bond of CH₄. The metal, as an electron donor, undergoes the change from Me^{1+x} to Me^x during the reaction. Furthermore, hydroxyl radical (•OH) can be generated to attack the C-H bond to generate •CH₃ on metal-modified catalysts.

There are many by-products in the NOCM process, and the conversion efficiency of CH₄ is still relatively low. Thus, further research is warranted. In view of this, we propose the following methods for creating a photocatalyst for the NOCM reaction: (1) Developing in-situ technologies, such as X-ray Absorption Fine Structure (XAFS), X-ray Photoelectron

Spectroscopy (XPS), and Diffuse Reflectance Fourier Transform Infrared Spectroscopy (DRIFTS), to investigate the structural changes of intermediates and catalysts in an ultrashort time scale, which could help to distinguish between thermal and photocatalytic effects. (2) The laboratory typically utilizes Xe lamps as the solar energy source, limiting the use of sunlight of different wavebands. To improve the efficiency of solar energy conversion and utilization, researchers could consider using solar simulators for indoor testing, or solar concentrators to directly convert and utilize solar energy. (3) More research should focus on bimetallic catalysts to improve C_2H_6 selectivity by exploiting the synergistic effects of different metals. It is important to further elucidate the reaction mechanism of cocatalysts.

Author Contributions: J.W. and Z.R. contributed equally. Editing and review, J.W. and Z.R.; Review, Y.C.; Supervision, F.W., Z.H. and Y.Z. All authors have read and agreed to the published version of the manuscript.
