Abstract: In this paper, we propose various kinds of two-way multi-antenna relaying with simultaneous wireless information and power transfer (SWIPT) and investigate their performance. Specifically, we first consider a two-way relay network where two single-antenna end nodes communicate with each other through a multi-antenna relay node that is energy constrained. This relay node harvests energy from the two end nodes and use the harvested energy for forwarding their information. Six relaying schemes that support the considered network then build on the power splitting-based relaying and time switching-based relaying protocols. The average bit error rates of these schemes are evaluated and compared by computer simulations considering several network parameters, including the number of relay antennas, power splitting ratio, and energy harvesting time. Such evaluation and comparison provide useful insights into the performance of SWIPT-based two-way multi-antenna relaying.

Keywords: amplify-and-forward; bit error rate; decode-and-forward; network coding; simultaneous wireless information and power transfer (SWIPT); space-time coding; two-way multi-antenna relaying

1. Introduction

Recently, simultaneous wireless information and power transfer (SWIPT) has gained great interest due to its capability to deal with the energy scarcity in energy-constrained wireless networks [1–10]. In the seminal works [1,2], the fundamental trade-off between information and power transfer in different point-to-point wireless channels was studied. On the other hand, two practical receiver designs for SWIPT, namely power splitting (PS) and time switching (TS), were firstly presented in [3,4]. Specifically, the PS-based receiver splits the received radio-frequency signal into two streams of different power for harvesting energy and decoding information, whereas the TS-based receiver switches over time between those two operations. The SWIPT has been adopted later in more complicated communication scenarios, including the broadband wireless system [5], the cellular network [6], the interference channel [7,8], and the relay channel [9,10]. This paper focuses on the last scenario.

Many works in the literature (e.g., [11–15]) have been devoted to two-way multi-antenna relaying (without SWIPT) as this approach can not only extend communication range but also improve spectral efficiency. In a basic two-way multi-antenna relay network (see Figure 1), an intermediate relay node equipped with multiple antennas is used to assist two end nodes in exchanging their information. Nevertheless, application of SWIPT to this kind of network is still in its infancy [16–18]. In [16], the SWIPT-based beamforming design for a multi-antenna relay was considered to maximize the sum rate of its two-way relay network. In [17], the authors presented a three-phase two-way relay network where an energy-constrained multi-antenna relay node harvests energy from a pair of single-antenna source nodes, and presented an optimal power allocation solution. In [18], an optimal joint source
and relay beamforming scheme for two-way multi-antenna relay networks with SWIPT was proposed based on the principle of singular value decomposition.

![Figure 1. System model.](image)

Depending on the nature and complexity of relays, relaying schemes can be classified into two main categories: non-regenerative relaying and regenerative relaying [19]. Non-regenerative relaying generally implies that the relays only amplify their received signals before retransmitting them. Then, it is often referred to as amplify-and-forward (AF) relaying in the literature. Note that all existing works on two-way multi-antenna relaying with SWIPT (i.e., [16–18]) are non-regenerative. On the other hand, regenerative relaying requires the relays to change the waveforms and/or the data contents by performing some processing in the digital domain. An example is the decode-and-forward (DF) relay, which receives the data from its immediate predecessor, decodes, re-encodes, and finally retransmits it. To the best of our knowledge, regenerative relaying has not yet been considered in the SWIPT-based two-way multi-antenna relay networks.

In this paper, we consider a two-way relay network in which two single-antenna end nodes communicate with each other through a multi-antenna relay node that is energy constrained. This relay node harvests energy from the two end nodes and use the harvested energy for forwarding their information. Based on two half-duplex relaying protocols, called power splitting-based relaying (PSR) and time switching-based relaying (TSR) [9], for separate energy harvesting and information processing at the relay node, six multiple-antenna relaying schemes, namely PS-AF, PS-DF, PS-DF with space-time coding (PS-DF-STC), TS-AF, TS-DF, and TS-DF-STC, are designed for the considered network. In the DF-oriented design, network coding (NC) [20] is applied to the end nodes’ information that is decoded at the relay node. Moreover, by having multiple antennas at the relay node, STC [21] is used in the PS-DF-STC and TS-DF-STC schemes with the aim of achieving a better end-to-end decoding performance. Unlike the aforementioned works [16–18], which are devoted to analyzing the relevant sum-rate performance, this paper will investigate the average bit error rates (BERs) of the proposed relaying schemes as a function of the number of relay antennas, power splitting ratio, and energy harvesting time.

The remainder of this paper is organized as follows. Section 2 introduces the system model. Sections 3 and 4 present the PS-based and TS-based multiple-antenna relaying schemes, respectively. Section 5 compares the BER performance of these relaying schemes by simulations. Finally, Section 6 concludes the paper.

Notation: Bold upper-case letters denote matrices and bold lower-case letters denote column vectors. \([ij,·]_T, ·^H, \text{ and } (·)^{-1}\) denote the \((i,j)\)-th element, transpose, conjugate transpose, and inverse of a matrix, respectively. \(\text{mod}(·) \text{ and } \text{demod}(·)\) denote the modulation and demodulation functions, respectively. \(|·|,\ E[·], \text{ and } \oplus\) denote the absolute value, the expectation value, and the bit-wise exclusive OR operator, respectively. \(Q(·), \text{erfc}(·), \Gamma(·), \text{and } _2F_1(·, ·; ·; ·)\) denote the Gaussian Q-function, complementary error function, ordinary Gamma function, Gauss hypergeometric function defined in (Equation (4.1), [22]), (p. xxxvi, [23]), (Equation (8.310.1), [23]), and (Equation (9.100), [23]), respectively. A circularly symmetric complex Gaussian random variable \(z\) with mean \(\mu\) and variance \(\sigma^2\) is denoted as \(z \sim CN(\mu, \sigma^2)\). In the case of communication over a slow-fading channel, the average BER for binary phase shift keying (BFSK) modulation is defined by (Equation (5.1), [22])
where \( f_\gamma(x) \) is the probability density function (PDF) of the instantaneous signal-to-noise ratio (SNR) of the received signal, \( \gamma \).

2. System Model

Consider a two-way relay network as shown in Figure 1, where end nodes \( T_1 \) and \( T_2 \), each of which is equipped with one antenna, exchange information through an energy-constrained intermediate relay node, \( R \), possessing \( M \) antennas. This relay node will harvest energy from the two end nodes and use the harvested energy for forwarding their information. The relay node’s antennas are spatially spaced in such a way that the received/transmitted signals undergo statistically independent fading. Throughout this paper, perfect timing and synchronization among \( T_1 \), \( T_2 \), and \( R \) are assumed, and BPSK modulation is used at \( T_1 \) and \( T_2 \). Let \( h_{1,m} \sim CN(0, \sigma^2_1) \) (or \( h_{2,m} \sim CN(0, \sigma^2_2) \) ) denote the channel gain between the antenna of \( T_1 \) (or \( T_2 \)) and the \( m \)-th antenna of \( R \), where \( \sigma^2_1 = d_{1,v}^{-\nu} \) (or \( \sigma^2_2 = d_{2,v}^{-\nu} \)) is due to the path loss with power path loss exponent \( \nu \) and distance \( d_1 \) (or \( d_2 \)) of the \( T_1 \) – \( R \) link (or the \( T_2 \) – \( R \) link), and \( m = 1, 2, ..., M \). We presume that all the channels are static over an interval of \( 2N \), which denotes the total block time in which a certain block of information is exchanged between \( T_1 \) and \( T_2 \) (see Figures 2a and 3a), and ignore the direct link between the end nodes owing to the larger distance compared with the \( T_1 \) – \( R \) and \( T_2 \) – \( R \) links [16]. For analytical simplicity, we assume that the relay node is located halfway between the end nodes, and thus \( \sigma^2_1 = \sigma^2_2 = \sigma^2 \). As mentioned in Section 1, we consider two half-duplex relaying protocols for separate energy harvesting and information processing at the relay node, i.e., PSR and TSR.

3. PSR Protocol

Figure 2 illustrates the key parameters in the PSR protocol for energy harvesting and information processing at the relay node \( R \) and the block diagram of the corresponding receiver. In Figure 2a, the first block time \( N \) is used for multiple access (MA) where the end nodes \( T_1 \) and \( T_2 \) transmit their signals simultaneously, and \( P \) is the total signal power. In the second block time \( N \), the relay node processes this signal (according to the schemes that will be presented below) and broadcasts it. During the MA phase, the fraction of the received signal power \( \rho P \) is used for energy harvesting, and the remaining received power \( (1 - \rho)P \) is used for information transmission, where \( 0 < \rho < 1 \) is the power splitting ratio. In other words, as shown in Figure 2b, the portion of the received radio-frequency (RF) signal, denoted by \( \sqrt{\rho y_{t,m}} \), is sent to the energy harvesting receiver and the remaining signal strength, denoted by \( \sqrt{1 - \rho y_{t,m}} \), drives the information receiver. In the following, we describe three multiple-antenna relaying schemes, which correspond to the PSR protocol.

![Figure 2](image-url)
3.1. PS-DF Scheme

In the MA phase, the received RF signal at the relay node can be modeled as:

\[
y_r = \begin{bmatrix}
y_{r,1} \\
y_{r,2} \\
\vdots \\
y_{r,M}
\end{bmatrix} = \begin{bmatrix}
\sqrt{P_1}h_{1,1}x_1 + \sqrt{P_2}h_{2,1}x_1 + n_{r,1}^a \\
\sqrt{P_1}h_{1,2}x_1 + \sqrt{P_2}h_{2,2}x_2 + n_{r,2}^a \\
\vdots \\
\sqrt{P_1}h_{1,M}x_1 + \sqrt{P_2}h_{2,M}x_2 + n_{r,M}^a
\end{bmatrix}
\]

\[
= \begin{bmatrix}
\sqrt{P_1}h_1 \\
\sqrt{P_2}h_2
\end{bmatrix} \begin{bmatrix}
x_1 \\
x_2
\end{bmatrix} + \begin{bmatrix}
n_{r,1}^a \\
n_{r,2}^a \\
\vdots \\
n_{r,M}^a
\end{bmatrix}
\]

where \( P_1 = \zeta_1 P \) and \( P_2 = \zeta_2 P \) are the transmitted power from \( T_1 \) and \( T_2 \), respectively; \( 0 < \zeta_1, \zeta_2 < 1 \) are the power ratios of \( T_1 \) and \( T_2 \), respectively (i.e., \( \zeta_1 + \zeta_2 = 1 \)); \( x_1 \) and \( x_2 \) are the normalized information signals from \( T_1 \) and \( T_2 \), respectively (i.e., \( E \left| x_1 \right|^2 = E \left| x_2 \right|^2 = 1 \)); and \( n_{r,m}^a \sim \text{CN}(0, \sigma_a^2) \) is the additive white Gaussian noise (AWGN) at the \( m \)-th antenna of \( R \). The energy harvesting receiver in Figure 2b rectifies the RF signal \( \sqrt{P_{r,m}} \) directly and gets the direct current to charge up the battery. Therefore, the harvested energy at the \( m \)-th antenna of the relay node during the MA phase is given by:

\[
E_m = \eta \rho N \left( P_{0} r^2 + \sigma_a^2 \right), \quad m = 1, 2, ..., M
\]

where \( 0 < \eta \leq 1 \) is the energy conversion efficiency (which depends on the rectification process and the energy harvesting circuitry [9]). Meanwhile, the information receiver in Figure 2b down-converts the RF signal \( \sqrt{1 - \rho}y_{r,m} \) to baseband and processes the baseband signal, where \( n_{r,m}^{(c)} \sim \text{CN}(0, \sigma_c^2) \) is the AWGN due to RF-band-to-baseband signal conversion. After down conversion, the sampled baseband signal vector at the relay node is given by:

\[
\tilde{y}_r = \sqrt{1 - \rho}y_r + n_r^{(c)}
\]

\[
= \sqrt{1 - \rho} \left( \begin{bmatrix}
\sqrt{P_1}h_1 \\
\sqrt{P_2}h_2
\end{bmatrix} \begin{bmatrix}
x_1 \\
x_2
\end{bmatrix} + \begin{bmatrix}
n_{r,1}^a \\
n_{r,2}^a \\
\vdots \\
n_{r,M}^a
\end{bmatrix} \right) + n_r^{(c)}
\]

\[
= \Psi \begin{bmatrix}
x_1 \\
x_2
\end{bmatrix} + n_r.
\]

Assuming that \( \rho, P_1, P_2, \{h_{1,m}\}_{m=1}^M, \) and \( \{h_{2,m}\}_{m=1}^M \) are known at the relay node and applying zero-forcing (ZF) detection, estimates of \( x_1 \) and \( x_2 \), denoted by \( \hat{x}_1 \) and \( \hat{x}_2 \), respectively, are obtained as:

\[
\begin{bmatrix}
\hat{x}_1 \\
\hat{x}_2
\end{bmatrix} = \left( \Psi^H \Psi \right)^{-1} \Psi \tilde{y}_r
\]
(For discussions of how the relay node can obtain \( \{h_{1,m}\}_{m=1}^{M} \) and \( \{h_{2,m}\}_{m=1}^{M} \), interested readers are referred to [24,25]).

Let \( \gamma_{ir} \) denote the instantaneous SNR of \( \hat{x}_i \), where \( i = 1, 2 \). It is straightforward to show that:

\[
\gamma_{ir} = \frac{1}{(1-\rho)\sigma_a^2 + \sigma_b^2} \left| \frac{1}{2} \sum_{m=1}^{M} |h_{1,m}|^2 \right|^2,
\]

where the second equality is obtained by using the fact that (Equation (8.359.3), [23]), and the fourth equality is obtained by using (Equation (6.455.1), [23]).

Specifically, let \( \hat{x}_i = \frac{\sum_{m=1}^{M} \frac{1}{2} |h_{1,m}|^2 \hat{x}_{1i} + \sum_{m=1}^{M} |h_{2,m}|^2 \hat{x}_{2i}}{\sum_{m=1}^{M} |h_{1,m}|^2} \).

Hence, the corresponding average BER can be derived as follows:

\[
\bar{T}_{e,ir} = \int_{0}^{\infty} Q\left( \sqrt{2x} \right) f_{\gamma_{ir}}(x) \ dx
\]

\[
= \frac{1}{2\sqrt{\pi}} \int_{0}^{\infty} \Gamma\left( \frac{1}{2}, x \right) f_{\gamma_{ir}}(x) \ dx
\]

\[
= \frac{1}{2\sqrt{\pi} \Gamma(M-1, \sigma_{\gamma_{ir}}^2)} \times \int_{0}^{\infty} x^{M-2} \exp\left( -\frac{(1-\rho)\sigma_b^2 + \sigma_a^2}{(1-\rho)\sigma_b^2 + \sigma_a^2} x \right) \ dx
\]

\[
= \frac{\sigma_a^2}{(1-\rho)\sigma_b^2 + \sigma_a^2} \left[ 1, M - \frac{1}{2}, M; \frac{(1-\rho)\sigma_b^2 + \sigma_a^2}{(1-\rho)\sigma_b^2 + \sigma_a^2} \right]
\]

where the second equality is obtained by using the fact that \( Q(x) = \text{erfc}(x/\sqrt{2})/2 \) and (Equation (8.359.3), [23]), and the fourth equality is obtained by using (Equation (6.455.1), [23]).

The relay node then performs NC of \( \hat{x}_1 \) and \( \hat{x}_2 \) at bit level to obtain the composite signal. Specifically, let \( \hat{b}_i = \text{demod}(\hat{x}_i) \) be the estimated information bit sequence corresponding to \( \hat{x}_i \), where \( i = 1, 2 \). The composite signal is given by \( x_r = \text{mod}(\hat{b}_1 \oplus \hat{b}_2) \). As in [9], we assume that the processing power required by the transmit/receive circuitry at the relay node is negligible as compared to the power used for transmitting the composite signal in the broadcast (BC) phase. From Equation (3), the latter power is given by:

\[
P_r = \frac{1}{N} \sum_{n=1}^{N} E_m
\]

\[
= \eta P_M \left( P_s^2 + \sigma_a^2 \right)
\]

and the sampled received (baseband) signal at the end node \( T_i \) (\( i = 1, 2 \)) in the BC phase can be expressed as:

\[
y_i = \sqrt{P_r} \sum_{m=1}^{M} h_{i,m} x_r + n_{i}^{[a]} + n_{i}^{[c]}
\]
where \( n_i^{[a]} \sim CN(0, c_a^2) \) and \( n_i^{[c]} \sim CN(0, c_c^2) \) are the AWGN due to the antenna and that due to RF-band-to-baseband signal conversion, respectively. Assuming that \( \{ h_{i,m} \}^M_{m=1} \) is known at \( T_i \), an estimate of \( x_r \) is obtained as:

\[
\hat{x}_r = \frac{y_i}{\sum_{m=1}^{M} h_{i,m}}
\]

\[
= \sqrt{p_c} x_r + \frac{n_i^{[a]} + n_i^{[c]}}{\sum_{m=1}^{M} h_{i,m}}
\]

(For realizing this assumption, interested readers may consult [24,25]).

Denoting by \( \gamma_{ri} \) the instantaneous SNR of \( \hat{x}_r \) at \( T_i \), it can be shown that:

\[
\gamma_{ri} = \frac{p_c \sum_{m=1}^{M} h_{i,m}^2}{\sigma_a^2 + \sigma_c^2}
\]

Denoting by \( \beta := \left| \sum_{m=1}^{M} h_{i,m} \right|^2 \) and using (p. 48, [27]) and (Equations (5)–(8), [28]), the PDF of \( \beta \) can be expressed as:

\[
f_{\beta}(x) = \frac{1}{M\sigma^2} \exp \left( -\frac{x}{M\sigma^2} \right); \quad x \geq 0.
\]

From Equations (13) and (14), we have:

\[
f_{\gamma_r}(x) = \frac{\sigma_a^2 + \sigma_c^2}{\eta P M^2 \sigma^2(\sigma_a^2 + \sigma_c^2)} \exp \left( -\frac{(\sigma_a^2 + \sigma_c^2)}{\eta P M^2 \sigma^2(\sigma_a^2 + \sigma_c^2)} x \right); \quad x \geq 0.
\]

Following the same procedure as in (9), the average BER associated with \( \gamma_{ri} \) is obtained as:

\[
\overline{P}_{e,ri} = \frac{M\sigma(\sigma_a^2 + \sigma_c^2)(\eta P(\sigma_a^2 + \sigma_c^2))^{1/2}}{4[\eta P M^2(\sigma_a^2 + \sigma_c^2)]^{1/2}}
\times F_1(1, \frac{3}{2}, -\frac{2\sigma_c^2}{\eta P M^2(\sigma_a^2 + \sigma_c^2)}).
\]

At the end node \( T_i \), the intended signal \( x_j \) (\( i = 1, 2; j \neq i \)) can be finally recovered by performing bit-level network decoding of \( \hat{x}_r \) with its own signal \( x_j \), and the corresponding end-to-end BER can be obtained as:

\[
\overline{P}_{e} = \overline{P}_{e,\text{XOR}} (1 - \overline{P}_{e,n}) + \overline{P}_{e,ri} (1 - \overline{P}_{e,\text{XOR}})
\]

\[
= \overline{P}_{e,\text{XOR}} + \overline{P}_{e,ri} - 2\overline{P}_{e,\text{XOR}}\overline{P}_{e,ri}
\]

where:

\[
\overline{P}_{e,\text{XOR}} = \overline{P}_{e,1r} (1 - \overline{P}_{e,2r}) + \overline{P}_{e,2r} (1 - \overline{P}_{e,1r})
\]

\[
= \overline{P}_{e,1r} + \overline{P}_{e,2r} - 2\overline{P}_{e,1r}\overline{P}_{e,2r}
\]

is the average BER of \( \hat{b}_1 \oplus \hat{b}_2 \).

### 3.2. PS-DF-STC Scheme

For the MA phase, the description of the signal transmissions from the end nodes \( T_1 \) and \( T_2 \) to the relay node \( R \) can be done as in the PS-DF scheme, i.e., Equations (2)–(4). The aforementioned ZF estimation and bit-level NC also follow. The corresponding average BER (i.e., \( \overline{P}_{e,ri} \) where \( i = 1, 2 \)) is therefore the same as Equation (9). However, instead of transmitting the same composite bit sequence \( b_r := \hat{b}_1 \oplus \hat{b}_2 \) simultaneously via \( M \) antennas in the BC phase, the relay node performs space-time block coding [21] for this sequence, as outlined in [29]. Specifically, let \( \textbf{B} \) be the space-time block-coded
composite bit matrix whose dimension is \( M \times L \), where \( L \) is the block length of the corresponding space-time block code. If \( N \) consecutive composite bits, i.e., \( b_1[k], b_1[k+1], \ldots, b_1[k+N-1] \), are transmitted with this matrix, then the code rate is \( N/L \). In this paper, we concentrate on the space-time block-coded composite bit matrices with the full code rate, i.e., \( L = N \). Such matrices for two, three, and four antennas are shown in Table 1.

<td>( \begin{bmatrix} h_{1,1} &amp; h_{1,2} &amp; h_{1,3} &amp; h_{1,4} \ h_{2,1} &amp; -h_{1,1} &amp; -h_{1,4} &amp; h_{1,3} \ h_{3,1} &amp; h_{1,4} &amp; -h_{1,1} &amp; -h_{1,2} \ h_{4,1} &amp; -h_{1,3} &amp; h_{1,2} &amp; -h_{1,1} \end{bmatrix} )</td>
</tr>
</tbody>
</table>

As a result, the sampled received (baseband) signal at the end node \( T_i \) \((i = 1, 2)\) in the BC phase can be expressed as:

\[
\begin{bmatrix} y_1[k] & y_1[k+1] & \cdots & y_1[k+N-1] \end{bmatrix} = \sqrt{T_x} \begin{bmatrix} x_1[k] & x_1[k+1] & \cdots & x_1[k+N-1] \end{bmatrix} H + \begin{bmatrix} n_1[k] & n_1[k+1] & \cdots & n_1[k+N-1] \end{bmatrix}
\]  

(19)

where \( H \) is exemplified in Table 1, and \( n_i \sim CN (0, \sigma_i^2 + \sigma^2) \) includes the antenna and signal-conversion AWGNs at the corresponding time instants. Following [30] and assuming that \( \{ h_{i,m} \}_{m=1}^M \) are known at \( T_i \), an estimate of \( \hat{x}_i[k], \hat{x}_i[k+1], \ldots, \hat{x}_i[k+N-1] \) can be obtained as

\[
\begin{bmatrix} \hat{x}_1[k] & \hat{x}_1[k+1] & \cdots & \hat{x}_1[k+N-1] \end{bmatrix} = \text{Re} \begin{bmatrix} y_1[k] & y_1[k+1] & \cdots & y_1[k+N-1] \end{bmatrix} H^H.
\]  

(20)

It is straightforward to show that the instantaneous SNR of \( \hat{x}_i \) at \( T_i \) is:

\[
\gamma_{ri} = \frac{P_\gamma \sum_{m=1}^M |h_{i,m}|^2}{\sigma_i^2 + \sigma^2} = \frac{P_\gamma \sum_{m=1}^M |h_{i,m}|^2}{\eta \rho M (\rho \sigma^2 + \sigma^2) \sum_{m=1}^M |h_{i,m}|^2}.
\]

(21)

Defining \( \theta := \sum_{m=1}^M |h_{i,m}|^2 \) and using (p. 48, [27]) and (Section “Related distributions”, [31]), the PDF of \( \theta \) can be expressed as:

\[
f_\theta(x) = \frac{x^{M-1}}{\Gamma(M)\sigma^{2M}} \exp\left(-\frac{x}{\sigma^2}\right); \ x \geq 0.
\]

(22)

From Equations (21) and (22), we have:

\[
f_{\gamma_{ri}}(x) = \frac{\left(\frac{\sigma_i^2 + \sigma^2}{\eta \rho M \sigma^2 + \sigma^2}\right)^M x^{M-1}}{\Gamma(M)\sigma^{2M}} \exp\left(-\frac{x}{\eta \rho M \sigma^2 + \sigma^2}\right); \ x \geq 0.
\]

(23)
Following the same procedure as in (9), the average BER associated with $\gamma_{ri}$ is obtained as:

$$\bar{P}_{e,ri} = \frac{\sigma^2 \Gamma(M+1/2)}{2\sigma^2 \Gamma(M+1)} \left( \frac{\eta \rho M}{\sigma^2 + \gamma^2} \right)^{M+1/2} \left( \frac{\gamma^2 + \rho M}{\sigma^2 + \gamma^2} \right)^{M+1/2} \times \frac{1}{2F_1 \left( 1, M + \frac{1}{2}; M + 1; \frac{\gamma^2 + \rho M}{\sigma^2 + \gamma^2} \right)}.$$  (24)

At the end node $T_i$, the intended signal $x_j (j = 1, 2; j \neq i)$ can be finally recovered by performing bit-level network decoding of $\hat{x}_r$ with its own signal $x_i$, and the corresponding end-to-end BER is obtained using Equation (17).

3.3. PS-AF Scheme

For the MA phase, the description of the signal transmissions from the end nodes $T_1$ and $T_2$ to the relay node $R$ can be done as in the PS-DF scheme, i.e., Equations (2)–(4). In the BC phase, the relay node amplifies and forwards the information signal as:

$$z_r = \frac{\tilde{y}_r}{||\tilde{y}_r||}$$  (25)

where $||\tilde{y}_r|| = \sqrt{(1 - \rho) \left( P_1 ||h_1||^2 + P_2 ||h_2||^2 + \sigma_2^2 \right) + 2\sigma_2^2}$ and the sampled received (baseband) signal at the end node $T_i$ ($i = 1, 2$) is given by:

$$y_i = \frac{\sqrt{P_i h_i^T \tilde{y}_r} + n_i^{[a]} + n_i^{[c]}}{||\tilde{y}_r||}$$

$$= \frac{\sqrt{(1 - \rho)P_i P_r} h_i^T h_1 x_1 + \sqrt{(1 - \rho)P_i P_r} h_i^T h_2 x_2 + \sqrt{(1 - \rho)P_i P_r} h_i^T h_1 h_2 x_1 + \sqrt{(1 - \rho)P_i P_r} h_i^T h_1 h_2 x_2}{||\tilde{y}_r||} + n_i^{[a]} + n_i^{[c]},$$  (26)

where $n_i^{[a]}$ and $n_i^{[c]}$ are defined below Equation (11). Assuming that $\rho$, $P_{tr}$, $\{h_{1,m}\}_{m=1}^{M}$, $\{h_{2,m}\}_{m=1}^{M}$, and $||\tilde{y}_r||$ are known at $T_i$, an estimate of the intended signal $x_j (j = 1, 2; j \neq i)$ can be obtained as:

$$\hat{x}_j = \frac{y_i - \sqrt{\rho (1 - \rho)P_i P_r h_i^T h_j x_i}}{\sqrt{(1 - \rho)P_i h_i^T h_j} / ||\tilde{y}_r||}.$$  (27)

Let $\gamma_{ji}$ denote the instantaneous SNR of $\hat{x}_j$ at $T_i$. It is straightforward to show that:

$$\gamma_{ji} = \frac{\sqrt{\rho (1 - \rho)P_i P_r M \sum_{m=1}^{M} |h_{1,m}|^2 |h_{2,m}|^2}}{(1 - \rho) \left( \frac{\sigma_2^2}{\gamma^2} \right) P_i \sum_{m=1}^{M} |h_{1,m}|^2 + (\sigma_2^2 + \rho M) \left( \frac{\sigma_2^2}{\gamma^2} \right) P_i \sum_{m=1}^{M} |h_{2,m}|^2 + \sigma_2^2 \right)}.$$  (28)

and the corresponding end-to-end BER, $\bar{P}_{e,ri}$, is the average BER associated with $\gamma_{ji}$. Unfortunately, it is difficult, if not impossible, to find the PDF of $\gamma_{ji}$. Therefore, the end-to-end BER has no closed-form expression and is obtained by means of simulations.

4. TSR Protocol

Figure 3 illustrates the key parameters in the TSR protocol for energy harvesting and information processing at the relay node $R$ and the block diagram of the corresponding receiver. In Figure 3a, $\alpha$ is the fraction of the total block time $2N$ in which the relay node harvests energy from the end nodes $T_1$ and $T_2$, where $0 \leq \alpha \leq 1$. The remaining block time $2(1 - \alpha)N$ is used for information transmission, such that the first half of that is used for MA and the second half is used for BC. Assuming that the TSR protocol has the same energy constraint as the PSR protocol, the power of the total received signal at
the relay node (during energy harvesting time and the MA phase) is $P' = P/(1 + \alpha)$. In what follows, we describe three multiple-antenna relaying schemes, which correspond to the TSR protocol.

**Figure 3.** (a) Key parameters in the TSR protocol for energy harvesting and information processing at the relay node; and (b) Block diagram of the relay receiver (with a focus on its $m$-th antenna) in the TSR protocol.

### 4.1. TS-DF Scheme

In the MA phase, the received RF signal at the relay node $R$ is the same as Equation (2) except that $P_1 = \zeta_1 P'$, $P_2 = \zeta_2 P'$, and the harvested energy during the energy harvesting time is given by:

$$E_m = \frac{2\eta N (P \sigma^2 + (1 + \alpha)\sigma_c^2)}{1 + \alpha}, \quad m = 1, 2, \ldots, M.$$  \hspace{1cm} (29)

After RF-band-to-baseband signal conversion at the information receiver as shown in Figure 3b, the sampled baseband signal vector is given by:

$$\tilde{y}_r = \begin{bmatrix} \sqrt{T_1 h_{1,1}} x_1 + \sqrt{T_2 h_{2,1}} x_1 + n_{r,1}^{[a]} + n_{r,1}^{[c]} \\ \sqrt{T_1 h_{1,2}} x_1 + \sqrt{T_2 h_{2,2}} x_1 + n_{r,2}^{[a]} + n_{r,2}^{[c]} \\ \vdots \\ \sqrt{T_1 h_{1,M}} x_1 + \sqrt{T_2 h_{2,M}} x_1 + n_{r,M}^{[a]} + n_{r,M}^{[c]} \\ \sqrt{T_1 h_{1,1}} x_2 + \sqrt{T_2 h_{2,1}} x_2 + n_{r,1}^{[a]} + n_{r,1}^{[c]} \\ \sqrt{T_1 h_{1,2}} x_2 + \sqrt{T_2 h_{2,2}} x_2 + n_{r,2}^{[a]} + n_{r,2}^{[c]} \\ \vdots \\ \sqrt{T_1 h_{1,M}} x_2 + \sqrt{T_2 h_{2,M}} x_2 + n_{r,M}^{[a]} + n_{r,M}^{[c]} \end{bmatrix} + \begin{bmatrix} n_{r,1}^{[a]} \\ n_{r,1}^{[c]} \\ \vdots \\ n_{r,M}^{[a]} \\ n_{r,1}^{[c]} \\ \vdots \\ n_{r,M}^{[c]} \end{bmatrix} + \begin{bmatrix} n_{r,1}^{[c]} \\ n_{r,2}^{[c]} \\ \vdots \\ n_{r,M}^{[c]} \end{bmatrix} \hspace{1cm} (30)$$

where $n_{r,m}^{[c]} \sim CN(0, \sigma_c^2)$ is the AWGN due to such conversion. Assuming that $P_1$, $P_2$, \{h_{1,m}\}_{m=1}^M$, and \{h_{2,m}\}_{m=1}^M are known at the relay node and applying ZF detection, estimates of the information signals $x_1$ and $x_2$, denoted by $\hat{x}_1$ and $\hat{x}_2$, respectively, are obtained as:

$$\begin{bmatrix} \hat{x}_1 \\ \hat{x}_2 \end{bmatrix} = (\Xi^{-1} \Xi)^{-1} \Xi \tilde{y}_r. \hspace{1cm} (31)$$
It is straightforward to show that the instantaneous SNR of \( \hat{x}_i \) is:

\[
\gamma_{ir} = \frac{1}{(1+\alpha)(\sigma^2_i + \sigma^2_c)} \left\{ \frac{\sum_{j=1}^{M} |h_{i,j}|^2}{\sum_{m=1}^{M} |h_{i,m}|^2} \right\}^{1/2} = \frac{\xi_i P^r \sum_{j=1}^{M} b_{i,j}^2}{(1+\alpha)(\sigma^2_i + \sigma^2_c) \sum_{m=1}^{M} |h_{i,m}|^2}
\]

(32)

where \( i = 1, 2 \). From Equations (7) and (32), we have:

\[
f_{\gamma_{ir}}(x) = \frac{(1+\alpha)(\sigma^2_i + \sigma^2_c)^{M-1}}{\Gamma(M-1)e^{2M-2} \left( \xi_i P^r \right)^{M-1}} x^{M-2} \exp \left( -\frac{(1+\alpha)(\sigma^2_i + \sigma^2_c)}{\xi_i P^r} x \right); \quad x \geq 0.
\]

(33)

Following the same procedure as in Equation (9), the average BER associated with \( \gamma_{ir} \) is obtained as:

\[
\overline{P}_{e,ir} = \frac{\sigma \Gamma(M-1/2)(\xi_i P^r \sigma^2_i)^{1/2}(1+\alpha)(\sigma^2_i + \sigma^2_c)^{M-1}}{2\sqrt{\pi} \Gamma(M)(\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c))^{M-1/2}} \times \frac{1}{2} F_1 \left( 1, M - \frac{1}{2}; \frac{(1+\alpha)(\sigma^2_i + \sigma^2_c)}{\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c)} \right).
\]

(34)

Then, the corresponding composite signal \( x_r \) is created and broadcasted in the same way as in the PS-DF case. In the BC phase, the sampled received (baseband) signal at the end node \( T_i \) \((i = 1, 2)\) is the same as Equation (11) except that:

\[
P_r = \frac{\xi_i P^r \sum_{m=1}^{M} |h_{i,m}|^2}{2\xi_i M (\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c))}.
\]

(35)

Assuming that \( \{ h_{i,m} \}_{m=1}^{M} \) are known at \( T_i \), an estimate of \( x_r \) (i.e., \( \hat{x}_r \)) is obtained from Equation (12) together with Equation (35).

It can be shown that the instantaneous SNR of \( \hat{x}_r \) at \( T_i \) is:

\[
\gamma_{ri} = \frac{P_r \sum_{m=1}^{M} h_{i,m}^2}{\sigma^2_i + \sigma^2_c} = \frac{2\xi_i M (\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c)) \sum_{m=1}^{M} h_{i,m}^2}{(1+\alpha)(\sigma^2_i + \sigma^2_c)}.
\]

(36)

From Equations (14) and (36), we have:

\[
f_{\gamma_{ri}}(x) = \frac{(1-\alpha^2)(\sigma^2_i + \sigma^2_c)}{2\xi_i M \sigma^2_i (\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c))} \times \exp \left( -\frac{(1-\alpha^2)(\sigma^2_i + \sigma^2_c)}{2\xi_i M \sigma^2_i (\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c))} x \right); \quad x \geq 0.
\]

(37)

Following the same procedure as in Equation (9), the average BER associated with \( \gamma_{ri} \) is obtained as:

\[
\overline{P}_{e,ri} = \frac{\frac{M \alpha \sqrt{\sigma^2_i}}{\sigma^2_c \sigma^2_c}}{2\sqrt{\pi} \left( \frac{2\xi_i M \sigma^2_i (\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c))^{1/2}}{(1-\alpha^2)(\sigma^2_i + \sigma^2_c)} \right)} \times \frac{1}{2} F_1 \left( 1, \frac{3}{2}; 2; \frac{2\xi_i M \sigma^2_i (\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c))}{2\xi_i M \sigma^2_i (\xi_i P^r \sigma^2_i + (1+\alpha)(\sigma^2_i + \sigma^2_c))} \right).
\]

(38)

At the end node \( T_j \), the intended signal \( x_j (j = 1, 2; j \neq i) \) can be finally recovered by performing bit-level network decoding of \( \hat{x}_r \) with its own signal \( x_i \), and the corresponding end-to-end BER is obtained using Equation (17).
4.2. TS-DF-STC Scheme

For the MA phase, the description of the signal transmissions from the end nodes $T_1$ and $T_2$ to the relay node $R$ can be done as in the TS-DF scheme, i.e., Equations (2), (29) and (30). The aforementioned ZF estimation and bit-level NC also follow. The corresponding average BER (i.e., $P_{e,i}$ where $i = 1, 2$) is therefore the same as Equation (34). During the BC phase, the relay node performs full-rate space-time block coding for the resultant composite bit sequence and the end nodes perform the corresponding sequence decoding and signal recovery, as in the PS-DF-STC case.

It is straightforward to show that the instantaneous SNR of an estimate of $x_i$ at $T_i$ is:

$$\gamma_{ri} = \frac{P_i \sum_{m=1}^{M} |h_{i,m}|^2}{2\alpha P_i \sigma T_i \left( (1-\alpha^2)(e_r^2 + e_i^2) \right)}$$

(39)

From Equations (22) and (39), we have:

$$f_{\gamma_{ri}}(x) = \frac{\Gamma(M)(2\alpha P_i \sigma T_i \sigma M e_r^2)^{1/2} \left( (1-\alpha^2)(e_r^2 + e_i^2) \right)^{M-1}}{\Gamma(M)(2\alpha P_i \sigma T_i \sigma M e_r^2)^{1/2} \left( (1-\alpha^2)(e_r^2 + e_i^2) \right)^{M-1}} \times \exp \left( -\frac{\gamma_{ri} x}{2\alpha P_i \sigma T_i \sigma M e_r^2} \right); \ x \geq 0$$

(40)

Following the same procedure as in Equation (9), the average BER associated with $\gamma_{ri}$ is obtained as:

$$P_{e,ri} = \frac{\sigma \Gamma(M+1/2) \left( 2\alpha P_i \sigma T_i \sigma M e_r^2 \right)^{1/2} \left( (1-\alpha^2)(e_r^2 + e_i^2) \right)^{M-1}}{\Gamma(M)(2\alpha P_i \sigma T_i \sigma M e_r^2)^{1/2} \left( (1-\alpha^2)(e_r^2 + e_i^2) \right)^{M-1/2}} \times 2F1 \left( 1, M + \frac{1}{2}; M + 1; \frac{\gamma_{ri}}{2\alpha P_i \sigma T_i \sigma M e_r^2} \right).$$

(41)

The corresponding end-to-end BER is obtained using Equation (17).

4.3. TS-AF Scheme

For the MA phase, the description of the signal transmissions from the end nodes $T_1$ and $T_2$ to the relay node $R$ can be done as in the TS-DF scheme. In the BC phase, the relay node amplifies and forwards the information signal as expressed in Equation (25), where:

$$\|\tilde{y}_i\| = \sqrt{P_1 \|h_1\|^2 + P_2 \|h_2\|^2 + Mc_a^2 + Mc_e^2}$$

(42)

and the sampled received (baseband) signal at the end node $T_i$ ($i = 1, 2$) is given by:

$$y_i = \sqrt{P_r} h_i^T \tilde{y}_i + n_i^{[a]} + n_i^{[c]}$$

$$= \frac{\sqrt{P_r} \|h_i\|^2}{\|y_i\|} h_i^T x_1 + \frac{\sqrt{P_r} \|h_i\|^2}{\|y_i\|} h_i^T x_2 + \frac{\sqrt{P_r} \|h_i\|^2}{\|y_i\|} h_i^T n_i^{[a]} + \frac{\sqrt{P_r} \|h_i\|^2}{\|y_i\|} h_i^T n_i^{[c]} + n_i^{[a]} + n_i^{[c]}$$

(43)

where $n_i^{[a]}$ and $n_i^{[c]}$ are defined below Equation (11). Assuming that $P_r$, $\{h_{1,m}\}_{m=1}^{M}$, $\{h_{2,m}\}_{m=1}^{M}$, and $\|\tilde{y}_i\|$ are known at $T_i$, an estimate of the intended signal $x_j$ ($j = 1, 2; j \neq i$) can be obtained as:

$$\hat{x}_j = \frac{y_j - \sqrt{P_r} \|h_i\|^2}{\|y_i\|} h_i^T x_j / \|y_i\|.$$
Let $\gamma_{ji}$ denote the instantaneous SNR of $\hat{x}_j$ at $T_i$. It is straightforward to show that:

$$
\gamma_{ji} = \frac{P_r P_t \left| \sum_{m=1}^{M} h_{i,m} \right|^2}{(\sigma_a^2 + \sigma_e^2) \left( P_r \sum_{m=1}^{M} |h_{i,m}|^2 + P_t \sum_{m=1}^{M} |h_{1,m}|^2 + P_2 \sum_{m=1}^{M} |h_{2,m}|^2 + M \sigma_a^2 + M \sigma_e^2 \right)}
$$

(45)

and the corresponding end-to-end BER, $P_{e_{ji}}$, is the average BER associated with $\gamma_{ji}$. Unfortunately, it is difficult, if not impossible, to find the PDF of $\gamma_{ji}$. Therefore, the end-to-end BER has no closed-form expression and is obtained by means of simulations.

5. Simulation Results

In this section, we evaluate the performance of the proposed multiple-antenna relaying schemes (i.e., PS-DF, PS-DF-STC, PS-AF, TS-DF, TS-DF-STC, and TS-AF) in terms of average BER of the end nodes $T_1$ and $T_2$. Suppose that $T_1$ and $T_2$ are separated by a distance of 2 m, and the relay $R$ is located halfway between them. Unless stated otherwise, we set the total signal power, $P = 1$ W; the power ratios of $T_1$ and $T_2$, $\xi_1$, $\xi_2 = 0.5$; the path loss exponent, $\nu = 2.7$; the power energy conversion efficiency, $\eta = 1$; the power splitting ratio in the PSR protocol, $\rho = 0.5$; and the time fraction used for energy harvesting in the TSR protocol, $\alpha = 0.5$.

The simulated BERs of the PS-DF, PS-DF-STC, and PS-AF schemes are plotted versus antenna noise variance $\sigma_a^2$ for different numbers of relay antennas $M$ (with fixed conversion noise variance $\sigma_e^2 = 0.01$) in Figure 4 and versus conversion noise variance $\sigma_e^2$ for different values of $M$ (with fixed antenna noise variance $\sigma_a^2 = 0.01$) in Figure 5. The theoretical BER curves of the PS-DF scheme (computed with Equations (9), (16), and (17)) and the PS-DF-STC scheme (computed with Equations (9), (17), and (24)) are also included and labeled with “(theor.)”. We can see that the theoretical results perfectly match their simulation counterparts, which verifies the BER formulae derived in Sections 3.1 and 3.2. Similarly, the results for the TS-DF, TS-DF-STC, and TS-AF cases are shown in Figures 6 and 7. As seen, the theoretical BER results (computed with Equations (17), (34), and (38) for the TS-DF case, and with Equations (17), (34), and (41) for the TS-DF-STC case) agree well with the simulated ones, which validates the BER analysis in Sections 4.1 and 4.2. It is clear that increasing the number of relay antennas generally improves the BER performance (the results at $M = 3$ are excluded to make the BER curves readable in all these figures). From Figures 4 and 5, we can see that the BERs of the PS-DF, PS-DF-STC, and PS-AF schemes are comparable when $M = 2$, and their difference becomes significant when $M = 4$. In the latter case, the PS-DF-STC scheme performs best while the PS-AF scheme does worst. Similar performance trends can be observed in the TS-DF, TS-DF-STC, and TS-AF schemes, as illustrated in Figures 6 and 7. Comparing Figures 4 and 6 (or Figures 5 and 7), one can find that, with the same number of relay antennas, the TS-DF and TS-AF schemes are generally superior to the PS-DF and PS-AF schemes, respectively.

It would be interesting to study the effect of the power allocation parameters, i.e., power splitting ratio $\rho$ and energy harvesting time $\alpha$, on the BER performance. To this end, we show in Figure 8 the BER as a function of $\rho$ for the PS-DF, PS-DF-STC, and PS-AF schemes, and in Figure 9 the BER as a function of $\alpha$ for the TS-DF, TS-DF-STC, and TS-AF schemes. From these two figures, we observe that, in general, equal power allocation, i.e., $\rho, \alpha = 0.5$, is a good strategy for the PS-AF and TS-AF schemes. However, the optimal $\rho$ and $\alpha$ which minimize the BERs of the PS-DF and TS-DF schemes, respectively, depend mainly on the number of relay antennas $M$. Specifically, these optimal $\rho$ and $\alpha$ increase (toward 1) as $M$ increases. For example, the optimal $\rho$ for the two-antenna PS-DF scheme is approximately 0.26 while that for the four-antenna PS-DF scheme is around 0.65 (See Figure 8). In addition, the optimal $\rho$ for the two-antenna PS-DF-STC scheme (or the optimal $\alpha$ for the two-antenna TS-DF-STC scheme) is nearly the same as that for the four-antenna PS-DF-STC scheme (or that for the
four-antenna TS-DF-STC scheme). This result indicates that these optimal \( \rho \) and \( \alpha \) are not sensitive to the value of \( M \), unlike those for the PS-DF and TS-DF schemes, respectively.

**Figure 4.** BER versus antenna noise variance \( \sigma_a^2 \) for the PS-DF, PS-DF-STC, and PS-AF schemes (conversion noise variance \( \sigma_c^2 = 0.01 \) and power splitting ratio \( \rho = 0.5 \)).

**Figure 5.** BER versus conversion noise variance \( \sigma_c^2 \) for the PS-DF, PS-DF-STC, and PS-AF schemes (antenna noise variance \( \sigma_a^2 = 0.01 \) and power splitting ratio \( \rho = 0.5 \)).
Figure 6. BER versus antenna noise variance $\sigma_a^2$ for the TS-DF, TS-DF-STC, and TS-AF schemes (conversion noise variance $\sigma_c^2 = 0.01$ and energy harvesting time $\alpha = 0.5$).

Figure 7. BER versus conversion noise variance $\sigma_c^2$ for the TS-DF, TS-DF-STC, and TS-AF schemes (antenna noise variance $\sigma_a^2 = 0.01$ and energy harvesting time $\alpha = 0.5$).
Figure 8. BER versus power splitting ratio $\rho$ for the PS-DF, PS-DF-STC, and PS-AF schemes (antenna noise variance $\sigma_a^2 = 0.01$ and conversion noise variance $\sigma_c^2 = 0.01$).

Figure 9. BER versus energy harvesting time $\alpha$ for the TS-DF, TS-DF-STC, and TS-AF schemes (antenna noise variance $\sigma_a^2 = 0.01$ and conversion noise variance $\sigma_c^2 = 0.01$).

To get a further insight into the impact of $M, \rho,$ and $\alpha,$ we plot the BER curves of the multiple-antenna relaying schemes with optimal power allocation (i.e., using the optimal $\rho$ or $\alpha$) in Figures 10–13. Comparing these results to those in Figures 4–7, we find that for all considered
relaying schemes except TS-AF scheme, the performance gain of the optimal power allocation over the equal power allocation can become significant as $M$ increases. Similar to the case of equal power allocation, the power optimization-based TS-DF and TS-AF schemes generally outperform their PS-DF and PS-AF counterparts, respectively.

Figure 10. BER versus antenna noise variance $\sigma_a^2$ for the PS-DF, PS-DF-STC, and PS-AF schemes (conversion noise variance $\sigma_c^2 = 0.01$ and optimal power splitting ratio).

Figure 11. BER versus conversion noise variance $\sigma_c^2$ for the PS-DF, PS-DF-STC, and PS-AF schemes (antenna noise variance $\sigma_a^2 = 0.01$ and optimal power splitting ratio).
Figure 11. BER versus conversion noise variance $c^2$ for the TS-DF, TS-DF-STC, and TS-AF schemes (conversion noise variance $c^2 = 0.01$ and optimal energy harvesting time).

Figure 12. BER versus antenna noise variance $\sigma^2$ for the TS-DF, TS-DF-STC, and TS-AF schemes (conversion noise variance $c^2 = 0.01$ and optimal energy harvesting time).

Figure 13. BER versus antenna noise variance $\sigma^2$ for the TS-DF, TS-DF-STC, and TS-AF schemes (antenna noise variance $\sigma^2 = 0.01$ and optimal energy harvesting time).
6. Conclusions

Based on two SWIPT protocols, namely TSR and PSR, we have presented various two-way multi-antenna relaying schemes, where an energy-constrained relay node harvests energy from two source nodes and uses that harvested energy to forward their information. We have compared the BER performance of these SWIPT-based relaying schemes, and have studied the effect of several network parameters, including the number of relay antennas, power splitting ratio, and energy harvesting time. The results have revealed that the benefit of multiple-antenna deployment at the relay depends primarily on the number of antennas (e.g., two antennas versus four antennas), the signal-processing technique (e.g., AF versus DF), and the power allocation strategy (e.g., equal power allocation versus optimal power allocation). In addition, despite the fact that the optimal power allocation is preferable to the equal power allocation, the latter seems an attractive choice for the PS-AF and TS-AF schemes. For the other relaying schemes (i.e., PS-DF, PS-DF-STC, TS-DF, and TS-DF-STC), algorithmic determination of the optimal power splitting ratio and optimal energy harvesting time (see, e.g., [32,33]) could be an interesting direction for future work.
