Abstract: We present preliminary results of the spectral analysis on the radial distributions of the star formation history in both a galaxy merger and a spiral isolated galaxy observed with MaNGA. We find that the central part of the isolated galaxy is composed by older stellar population (~2 Gyr) than in the outskirts (~7 Gyr). Also, the time-scale is gradually larger from 1 Gyr in the inner part to 3 Gyr in the outer regions of the galaxy. In the case of the merger, the stellar population in the central region is older than in the tails, presenting a longer time-scale in comparison to central part in the isolated galaxy. Our results are in agreement with a scenario where spiral galaxies are built from inside-out. In the case of the merger, we find evidence that interactions enhance star formation in the central part of the galaxy.

Keywords: interacting galaxies; isolated galaxies; peculiar galaxies

1. Introduction

From models, it is predicted that disks grow from inner to outer parts of galaxies, the so-called inside-out model of galaxy formation. This means that stars first form in the centre of galaxies and later in their outer regions. As a consequence, we expect to observe gradients in stellar age and metallicity as a function of galactic radius for spiral galaxies [1,2]. This effect is difficult to observe from photometry.
alone because of the age-metallicity degeneracy and the contamination of dust. Therefore, high spatial and spectral resolutions are required. In this regard, Sánchez et al. [3] find strong evidences of inside–out growth of the galaxy disk from the study of 7000 ionized regions, extracted from 306 galaxies observed by the CALIFA survey [4]. Integral Field Spectroscopy (IFS) is a powerful resource for understanding the physical mechanisms driven the formation and evolution of galaxies, and in particular, processes that drive the star formation. With the advent of the 3D spectroscopy, from IFS data, new observational results are available to explore galaxy assembly models [5–7]. Integral field unit (IFU) observations provide us with an added dimension to the information available for each galaxy. Clues to the nature of the physical processes that drive star formation in galaxies are encoded in the map. In this regard, MaNGA (Mapping Nearby Galaxies at Apache Point Observatory (http://www.sdss.org/surveys/manga/); [8]) is an integral field spectroscopic survey designed to investigate the internal kinematic structure and composition of gas and stars in an unprecedented sample of nearly 10,000 nearby galaxies. First results from the MaNGA prototype run are extremely promising. Li et al. [9] have detected radial gradients in the recent star formation histories of galaxies. Their results are consistent with the inside–out picture, but in order to interpret them in light of the predictions from theoretical models, it is necessary to separate the effects of the environment where galaxies are located. Galaxies suffer intrinsic evolution but they are also exposed to the influences of their local and large-scale environments. Do galaxies evolve by nature or by nurture? The observed properties of isolated galaxies are likely to be determined mainly by their initial formation conditions and secular evolutionary processes.

2. Experimental Section

2.1. Data

The sample of isolated galaxies used in this study is selected from the SDSS-based catalogue of Isolated Galaxies (SIG; [10]), which provided a representative sample of SDSS-selected isolated galaxies for testing galaxy evolution and secular processes in low density regions of the local Universe. These galaxies are isolated with no physical neighbours within a volume of $\Delta v \leq 500$ km·s$^{-1}$ and $d \leq 1$ Mpc projected radius, where $\Delta v$ is the absolute value of the line-of-sight velocity difference between the galaxy and its neighbours. In particular, we show preliminary results for SIG 2246, an almost face-on spiral isolated galaxy that has been already observed with MaNGA (see Figure 1a).
To study the radial distribution of the SFH we consider the stacked spectra in eight radial bins within 2 arcsec major axis elliptical annuli, as it is shown in the middle panel of Figure 1, over-plotted in the H\textsubscript{\alpha} map of the galaxy, which traces star formation. We consider ellipticity of the galaxy according to its value in the NASA-Sloan Atlas (NSA; Blanton M. http://www.nsatlas.org) catalogue.

**Figure 1.** Isolated galaxy SIG 2246. (a) SDSS three-colour image of the galaxy and the corresponding MaNGA IFU field of view; (b) MaNGA H\textsubscript{\alpha} map of the galaxy and the considered elliptical annuli bins. Flux units are per spatial pixel; (c) SFH for each radial bin, normalised to the IFU radii. Error bar in the Y-axis corresponds to the \textsigma of the Gaussian distribution in each radial bin. Error bar in the X-axis corresponds to radial bin length, manually divided by 3 to separately visualise each error bar (not as a continuum).

**Figure 2.** Interacting pair Mrk 848. (a) SDSS three-colour image of the object. Yellow circles correspond to the regions completely covered by the MaNGA IFU, meanwhile regions with red circles correspond to regions not covered or partially covered. (b) MaNGA H\textsubscript{\alpha} map of the galaxy merger. Flux units are per spatial pixel. (c) Estimated SFH for each selected region in colour-code according to the legend.
In order to test the methodology when considering galaxies in interaction, we selected Mrk 848, an observed galaxy merger listed in the MaNGA ancillary program on observing close pairs, which will be the largest IFU sample for pair/interacting galaxies in the nearby Universe. This galaxy merger shows two well defined tails (see Figure 2a), one in the north and other in the south, where the two nuclei are well identified in the central part. As it is shown in the left panel of Figure 2, the MaNGA IFU do not cover the full object, we therefore divided the merger into 6 regions. Yellow circles in the left panel of Figure 2 correspond to the regions where the MaNGA IFU completely covers the object, meanwhile red circles correspond to the regions out the IFU. Even if the region 2 is partially covered, we also considered the stacked spectra in that region to explore the SFH in the south tail.

2.2. Methodology

To elucidate how galaxies grow with time, one needs to recover the SFH, both in space and time, for individual galaxies. To constraint the SFH for the galaxies considered in our study we apply the so-called “fossil record method”. Physical properties of the stellar population of the observed spectra (i.e., age, metallicity, and dust attenuation) are then determined by comparing to a modelled spectra. To create a modelled spectral energy distribution (SED) we apply the evolutionary synthesis modelling technique, considering that the SFH follows a determined distribution. For the purpose of this study, based on the inside-out model of galaxy formation, we assume that the SFR of the galaxy vary with time following a Gaussian distribution [11].

Since a single stellar population (SSP) does not reproduce well the stellar spectra, we use full spectrum modelling to model the SED as a combination of different SSPs, hereafter composite stellar population (CSP). Several models that provide SSPs can be found in the literature, one of the most commonly used is the model developed by Bruzual & Charlot [12], better known as the BC03 model. We adopted this model, assuming a Salpeter IMF [13] and we fix to solar metallicity as the starting point for this pilot study. Then, we model 100 CSPs where the SFH is parametrized by two free parameters $t_0$ and $\tau$, from 1 to 10 Gyr, which are the mean and sigma values of the Gaussian respectively.

The selection of a Gaussian distribution will allow an easier comparison of the physical parameters with the theoretical models. Then $t_0$ represents the mean age of the stellar population and $\tau$ represents the time-scale. We therefore estimate $t_0$ and $\tau$ by applying the fossil record method to the stacked spectra in each radial bin for the isolated galaxy, and to the stacked spectra in each region of the merger.

It is important to note that some sources of uncertainties arise when mapping of observed spectra to astrophysical information. Uncertainties come from the observed spectra (noise and calibration of the data), from synthesis models, and from the limitations of the spectral synthesis method [14]. Moreover, the information extracted from the multi stellar population modelling differs among implementations [15]. Since we present here a pilot study and some improvements will be implemented in modelling and full spectral fitting, we leave the analysis of the uncertainties for the future work.
3. Results and Discussion

3.1. SIG 2246

Following the methodology mentioned above, we constraint the SFH of the isolated galaxy SIG 2246. As it is shown in the right panel in Figure 1, we estimate the mean age of the average stellar population (blue points), in each radial bin considered, and the corresponding time-scale (error bars in the Y-axis).

In average, the central part of the galaxy is composed by older stellar population (∼2 Gyr) than in the outskirts (∼5 Gyr younger), where the most recent episode of star formation is not younger than 12 Gyr. Also, the time-scale is gradually larger from 1 Gyr in the inner part to 3 Gyr in the outer regions of the galaxy. This result is in agreement with the inside-out model of galaxy formation introduced in Section 1.

3.2. Mrk 848

We apply the same methodology to study the evolution of SIG 2246, to constraint the SFH in the galaxy merger Mrk 848. The left panel in Figure 2 shows the estimated SFH in each considered region of the object. The yellow and green Gaussian distributions correspond to the SFH in the centre (regions 3 and 4). The resulted SFH for regions 2, 5, and 6 correspond to the red, blue, and magenta distributions.

The stellar population in the central region is older than in the tails. If we base our interpretation on spiral galaxies forming under the inside-out model, then regions 3 and 4 correspond to the nuclei of each original spiral galaxy before merging. Therefore, the stellar populations in regions 2, 5, and 6 correspond, in average, to their spiral arms. Moreover, we find that they have the same mean stellar age, about 10 Gyr but different time-scales, where it is longer in the north tail.

We also find a long time-scale in the centre of the merger, even larger than the time-scale in the case of the study of SIG 2246. In comparison with the short time-scale in the isolated galaxy, this result suggests that interactions enhance the star formation in the central part of the galaxies.

4. Conclusions

We present preliminary results of the spectral analysis on the radial distributions of the star formation history in both a galaxy merger and a spiral isolated galaxy observed with MaNGA. Our main conclusions are the following:

(1) We presented preliminary results of the study of the evolution of SIG 2246, an almost face-on spiral isolated galaxy, using IFS from MaNGA, which is up to now the largest IFU survey for galaxies in the local Universe. We find a radial gradient in the SFH of SIG 2246. Our results are in agreement with a scenario where spiral galaxies are built from inside-out.

(2) We also apply the same methodology to study the SFH in the galaxy merger Mrk 848. We find evidence that interactions keep star formation in the central part of the galaxies.

Galaxies present gradients in SFH but also in their chemical enrichment history. According to this, we should take into account that our preliminary results could be biased by the fact that we modelled our
CSPs at a fixed solar metallicity. Different metallicities will be considered in the synthesis modelling for the future work.

We expect, for the very first time, to find some clues on how spiral galaxies form and evolve. To reach this goal, we will combine the observed galaxy properties, as result from the spectral fitting techniques, with the predictions from CEMs. First conclusions are expected after comparing the constrained SFH from models to the observed SFH. Results will elucidate what is the most plausible formation scenario. Therefore, we will not only say if galaxies formed by inside-out or not, we will also quantify it by comparing with CEMs.
