Abstract: The emerging interest in the search for alternatives to synthetic preservatives has led to various successful research studies exploring the use of yeasts as potential biological control agents and producers of biopreservatives. The findings that yeasts could be used as producers of biopreservatives lacked some engineering considerations regarding cost-effective process design for scale-up, although partial process optimization using renewable agro-waste has been achieved. This study investigated the biological stoichiometry and bioenergetic parameters during yeast growth and secondary metabolites production i.e., biopreservatives from non-*Saccharomyces* yeasts using grape pomace extract (GPE), a type of agro-waste, as a fermentation medium. This was achieved by reconfirming the optimum production conditions previously found for *Candida pyralidae* Y1117, *Pichia kluyveri* Y1125, and *Pichia kluyveri* Y1164 in GPE broth as a fermentation medium, conditions under which a high amount of yeast cells were obtained. High-density cell cultures were produced, from which the yeast cell pellets were harvested, dried, and combusted for the determination of elemental analysis, heat of combustion, biological stoichiometry, and bioenergetic parameters. This work generated biological stoichiometric models and bioenergetics information that could assist in the design of yeast biochemical conversion system when GPE is used as fermentation medium, thereby, addressing the biochemical engineering aspects that were lacking in a previous biopreservative production study using *Candida pyralidae* Y1117, *Pichia kluyveri* Y1125, and *Pichia kluyveri* Y1164.

Keywords: biopreservatives; biological stoichiometry; bioenergetics; grape pomace extract; yeasts

1. Introduction

The potential of yeasts as biological control agents and as producers of biopreservatives has been established by several independent studies [1–5]. However, those studies have been carried out in refined media with fewer biochemical engineering aspects for bioreactor designs and performance assessment for high-scale production. Recently, grape pomace extract (GPE) was explored as a readily available and cheap fermentation medium for the production of biopreservatives from yeasts [6]. The feasibility of a bioprocess engineering system and the related physiological conditions under which bioreactions can occur would only be possible by studying the biological thermodynamics of the process, in particular when considering industrial-scale production. This has not yet been applied

extensively in biological processes [7]. In addition, yield parameters can also be estimated during fermentation in order to assess the material and energy requirements in relation to the economic viability of any intended biological process [8–10]. Studying biological stoichiometry is also vital for establishing a control data set for system design and process control for the conversion of substrate by yeast, which is linked to secondary metabolite production using any renewable carbon source such as GPE as a fermentation medium. Akinpelu et al. [11] reported on the stoichiometric analysis of microbial growth and related yields for some biological processes. The production requirements in a bioreactor system in relation to the conversion of the growth-controlling substrate for extracellular compound production can be determined by the stoichiometric coefficients and bioenergetic analysis, which can better assist in elucidating the feasibility of a bioprocess system being designed and set a benchmark for other similar processes.

This can be achieved using conservation of mass, whereby microbial growth models can be applied for system parameter analysis. Several methods, such as that of half-reactions or irregularities can be used to evaluate the stoichiometric requirements of any conversion that takes place during microbial growth and bioproduct formation [9,11]. During the process of microbial conversion of substrates to extracellular compounds, catabolic and anabolic reactions occur. In the catabolic phase, the primary growth-controlling substrate such as glucose is broken down, and a portion of the catabolic product is then used in the anabolic phase for the synthesis of new biomass [9]. Table 1 depicts all the different equations that can be used to determine the parameters described above.

Table 1. Microbial growth parameters and the related models that describe the stoichiometric parameter analysis [9].

Parameter	Equation
Biological Stoichiometry	$\frac{1}{Y_{X/S}} S + Y_{A/X} A + Y_{N/X} NS \rightarrow X + Y_{P/X} P + Y_{C/X} CO_2$
Catabolic Reaction	$S + Y_A^{cat} A \rightarrow Y_P^{cat} P + Y_C^{cat} CO_2 \quad (\Delta G_{cat}^0)$
Anabolic Reaction	$Y_P^{ana} P + Y_C^{ana} CO_2 + Y_N^{ana} NS \rightarrow X + Y_A^{ana} A \quad (\Delta G_{ana}^0)$

S , A , NS , X , and P represent the substrate (energy source), electron acceptor, nitrogen source, dry biomass, and reduced electron acceptor, respectively.

Once stoichiometric requirements of a biological process have been determined, it is imperative to establish the energy requirements for the system. As substrates are being utilized as electron donors, accounting for the energy requirements means that parameters such as enthalpy of formation (ΔH_f^0), Gibbs energy (ΔG_f^0), and heat of reaction (ΔH_{RX}^0) are to be considered, with the Gibbs energy being the main driving force [7,9,12,13]. Therefore, the values for ΔG , ΔH , and ΔS can be estimated using Equation (1) [11].

$$\Delta G = \Delta H - T\Delta S \quad (1)$$

With ΔG , ΔH , and ΔS representing the Gibbs energy, enthalpy, and entropy changes, respectively.

Practically, this means that, for a bioreaction, experimental values for the formation of cells and the related heat of combustion are to be determined using Equation (2) [11].

$$\Delta H_C^{cell} \left(\frac{KJ}{mol} \right) = \Delta H_{cal}^{cell} \left(\frac{KJ}{g} \right) \times M_X \quad (2)$$

with ΔH_C^{cell} , ΔH_{cal}^{cell} , and M_X , representing the heat of combustion, calorimetric enthalpy of formation, and the mass of 1 C-mol of the dried biomass, respectively.

Once the heat of formation of biomass is obtained, the heat of reaction, as the result of the biosynthesis of 1 C-mol of biomass, can be estimated using Hess's law—see Equation (3):

$$\Delta H_{RX}^O = \sum n(\Delta H_{products}) - \sum n(\Delta H_{reactants}) \quad (3)$$

where n represents the respective stoichiometric molar coefficients.

The highest level of substrate conversion leading to the production of extracellular compounds, i.e., biopreservatives, occurred during the exponential growth phase of the yeast as described by Mewa-Ngongang et al. [14]. This study aimed to generate benchmarking biological stoichiometric and bioenergetics parameters during substrate utilization for growth of non-*Saccharomyces* yeasts and production of secondary metabolites using GPE, i.e., an agro-waste, as a fermentation medium, and to provide a set of requirements for the design of a biochemical conversion system. Such an assessment is scanty available in the literature, and in the future, biochemical processes could possibly use extracts from agro-waste as fermentation medium.

2. Materials and Methods

2.1. Microorganisms Selection, Culture Condition, and Inoculum Preparation

Candida pyralidae Y1117, *Pichia kluyveri* Y1125, and *Pichia kluyveri* Y1164 were selected based on their biopreservative production potential [6,14]. However, biological stoichiometric parameters, which are required for an engineering process design, were not found in the literature. *Dekkera bruxellensis*, a major spoilage organism for beverages, was used as the sensitive organism in the growth inhibition assay [6]. The yeast inoculums of *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 were prepared firstly by culturing on the grape pomace agar (GPA) for 2 days at 28 °C. The yeast cells were prepared by transferring a wire loop full of the culture into 5 mL of Yeast Peptone Dextrose (YPD) broth (Sigma Aldrich, South Africa) subsequent to incubation at 28 °C for 24 h. From the 24 h old yeast cultures, a volume of 1 mL was transferred to 150 mL sterile grape pomace extract broth (GPEB) diluted to 100 g L⁻¹ total sugar using sterile distilled water. The yeast-assimilable nitrogen content of the 100 g L⁻¹ total sugar GPEB was 0.074 g L⁻¹. The inoculated GPEB was subjected to incubation at 25 °C with agitation at 150 rpm, using a rotary shaker (LM-53OR, RKC Instrument Inc., Ohta-ku Tokyo, Japan) for 24 h [14].

2.2. Medium Preparation, Fermentation Condition, and Confirmation of Growth Inhibition Activity

An agro-waste-based medium using grape pomace extract (GPE) was prepared and used. Wet Chenin blanc grape pomace was collected in plastic buckets. The wet pomace was then further pressed at an increased pressure of up to 2 bars in order to extract the remaining juice, which was analyzed for sugar and nitrogen contents including pH. Total sugar and yeast-assimilable nitrogen concentrations of 150 and 0.136 g L⁻¹, respectively, and a pH of 3 were prepared. The fermentation for *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 was conducted as reported elsewhere [6]. Each yeast was cultured in a 4 L Erlenmeyer flask containing 1.3 L GPEB with three replicates. The growth inhibition activity of the crude biopreservatives from the three yeasts was evaluated and quantified using a plate assay method [6,14]. When *D. bruxellensis* was used as the sensitive organism, the concept of volumetric zone of inhibition (VZI) as reported by Mewa-Ngongang et al. [14] was used for growth inhibition activity quantification.

2.3. Biomass Preparation and Elemental Analysis

After fermentation, the yeast cultures were harvested by centrifugation at 10,000 rpm for 10 min at 4 °C. The resulting biomass pellets were washed three times with sterile distilled water and dried in a Duran[®] vacuum desiccator (DURAN Group GmbH, Germany). The process was repeated until a considerable amount of 10 g biomass was obtained. The wet cell pellets of *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 were picked

using a sterile spatula and placed into sterile glass Petri dishes. The cultures were then placed in an oven dryer set at 70 °C for 8 h and thereafter put in a desiccator at 28 °C for 3 days. Each plate was weighed twice a day to assess the fluid loss and to attain a constant weight. To remove residual moisture, the contents of the plates were transferred to sterile glass beakers and further dried in an oven at 50 °C until the weight became constant. The analysis of carbon (C), hydrogen (H), nitrogen (N), and sulfur (S) in the dried biomass was performed in three replicates for each yeast. The fraction corresponding to the percentage of oxygen was that of the remaining fraction after the sum of CHNS percentages was subtracted from 100.

2.4. Heat of Combustion Determination

An e2k Bomb calorimeter (Digital Data Systems Pty Ltd., Randburg, South Africa) was used to determine the heat of combustion of the dried biomass. The principle of general combustion was used, whereby the analyzer was set to combust the samples in three replicates in the presence of oxygen to form CO₂, H₂O, and N₂. The products of combustion were then separated using a gas chromatograph and then further analyzed by a thermal conductivity detector. The peaks obtained, corresponding to each compound (product of combustion), were integrated, and then the percentages of C, H, O, N, and S were calculated. Table 2 presents the heat of formation of reference compounds that were used to determine the heat of combustion for the dried biomass.

Table 2. Heat of formation at 298.15 K and 1 atm (101,325 kPa) of reference compounds used for the heat of combustion calculation during this study [12].

Substance	Formula	ΔH_f° (KJ/mol)
Glucose	C ₆ H ₁₂ O _{6(aq)}	−1263.07
Ammonia	NH _{3(aq)}	−80.29
Oxygen	O _{2(aq)}	−12.09
Water	H ₂ O _(l)	−285.83

2.5. Determination of Stoichiometric Molar Coefficients

The biomass yield, based on substrate consumption, was calculated to determine the number of moles of glucose utilized to form a yeast cell. A unit carbon per mole of glucose molecular weight (MW) of each yeast was then determined, which yielded the equations listed below, Equations (4)–(6), which were balanced using the law of conservation of mass based on the balances of the elemental molecular constituents.

C. pyralidae Y1117

P. kluyveri Y1125

P. kluyveri Y1164

3. Results

3.1. Confirmation of Growth Inhibition Activity

Based on previous research involving the yeasts selected for this work, it was deemed necessary to confirm the growth inhibition activity of the crude biopreservatives produced to ascertain the efficacy of the yeasts as biopreservative producers as previously reported [6].

The growth inhibition activities resulting from the three crude biopreservatives were indeed prominent, with a VZI of 0.78, 0.40, and 0.35 L VZI.mL⁻¹ BCU for *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164, respectively (Figure 1).

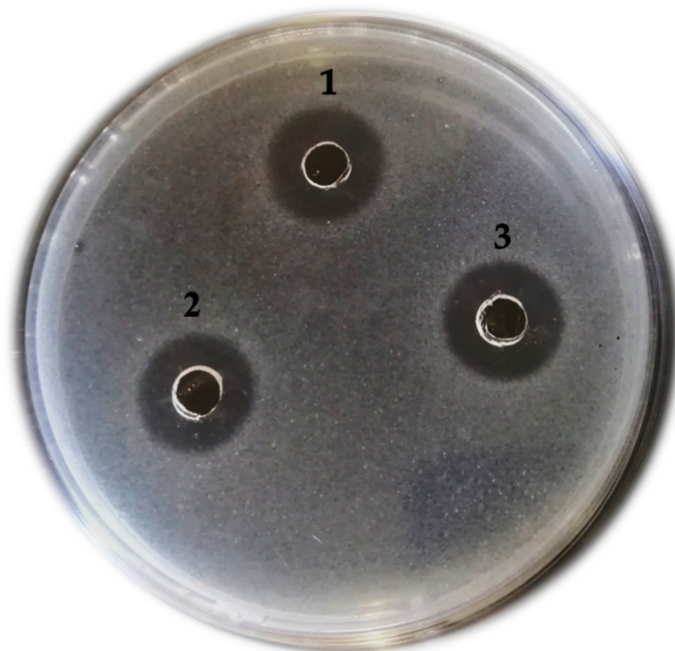

Figure 1. Growth inhibition activity of crude biopreservatives from *Candida pyralidae* Y1117 (1), *Pichia kluyveri* Y1125 (2), and *P. kluyveri* Y1164 (3) when *Dekkera bruxellensis* was used as the sensitive organism on a grape pomace extract medium.

3.2. Biomass Elemental Analysis

Table 3 shows the results of the elemental analysis of the dried cells mass belonging to *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164. Similar trends were observed for all three biopreservative-producing yeasts. Primarily, from the percentages of the elements analyzed, the averaged molecular weight and the unit carbon values (Table 3) were determined. The strain *P. kluyveri* Y1164 was the yeast with the highest carbon and hydrogen content, 44.149% and 6.871%, respectively, while *C. pyralidae* Y1117 and *P. kluyveri* Y1125 had a carbon content of 41.435% and 41.157%, respectively, and a hydrogen content of 6.582% and 6.484%, respectively. The nitrogen content of the dried biomass was similar, i.e., 7.200%, 6.333%, and 7.530%, for *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164, respectively. These results are comparable to what was observed by Akinpelu et al. [11] and Battley [12] in different studies. Previous studies also demonstrated that the contribution of other constituents including metal ions was negligible, thus not affecting the formulation of the MW [8,12]; however, their presence can have an effect not only on the composition in relation to the oxygen fraction of the biomass but also on the biomass performance.

Table 3. Elemental analysis, average molecular weight, and unit carbon mole of *Candida pyralidae* Y1117, *Pichia kluyveri* Y1125, and *P. kluyveri* Y1164 during biopreservation compound production using grape pomace extract as fermentation medium. The values presented in the table are the average of three replicates.

Yeast		[C]	[H]	[N]	[O]	[S]
<i>C. pyralidae</i> Y1117	%	41.435	6.582	7.200	44.501	0.282
	Average MW	3.453	6.582	0.514	2.781	0.009
	Unit-carbon	1.000	1.906	0.149	0.805	0.003
<i>P. kluyveri</i> Y1125	%	41.157	6.484	6.333	45.713	0.313
	Average MW	3.430	6.484	0.452	2.857	0.010
	Unit-carbon	1.000	1.891	0.132	0.833	0.003
<i>P. kluyveri</i> Y1164	%	44.149	6.871	7.530	41.104	0.346
	Average MW	3.679	6.871	0.538	2.569	0.011
	Unit-carbon	1.000	1.868	0.146	0.698	0.003

3.3. Determination of Stoichiometric Molar Coefficients

The stoichiometric molar coefficients for *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 are listed in Table 4. The MW of a unit carbon mole of each yeast was calculated from each of the elemental formulas. It was found that the MW of *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 were 28.968, 29.163, and 27.176 g C-mol⁻¹, respectively, which is in agreement with what has been reported by Akinpelu et al. [11]. The similarities of these findings with those of the published literature could be attributed to the use of renewable macro- and micronutrient-rich sources from agro-waste [11].

Table 4. Empirical, elemental formula and molecular weight of unit carbon mole of *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 during yeast growth and secondary metabolite production, i.e., biopreservatives using grape pomace extract as a fermentation medium.

	<i>C. pyralidae</i> Y1117	<i>P. kluyveri</i> Y1125	<i>P. kluyveri</i> Y1164
Empirical Formula	C _{3.454} H _{6.585} N _{0.514} O _{2.78} S _{0.009}	C _{3.453} H _{6.484} N _{0.452} O _{2.857} S _{0.010}	C _{3.679} H _{6.871} N _{0.538} O _{2.569} S _{0.011}
Elemental Formula	CH _{1.906} N _{0.149} O _{0.805} S _{0.003}	CH _{1.891} N _{0.132} O _{0.833} S _{0.003}	CH _{1.868} N _{0.146} O _{0.698} S _{0.003}
MW of Unit Carbon (g/C-mol)	28.968	29.163	27.176

After the unit carbon molecular weights for the yeasts, i.e., *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164, were determined, the biological stoichiometric equations were derived and balanced by determining the stoichiometric coefficients (a–f) using the conservation of mass approach (Table 5). The models used to represent and describe *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 metabolism per unit carbon mol during biochemical conversion of substrate for growth and secondary metabolite production i.e., biopreservatives using GPE as fermentation medium, are also presented in Table 5. The model equations were classified into three steps corresponding to the catabolic, anabolic, and metabolic reactions. Comparing these models to those reported in the literature, it was observed that there were some similarities, although these equations were generated from a different carbon source to those previously used; however, some of the processes were carried out using refined glucose and ammonia as energy sources for the fermentations. It was also observed that the three metabolic reaction models corresponding to the three biopreservative-producing yeasts were distinct from each other, which also justified the need to understand the different biochemical conversion ratios. During biochemical conversion, *P. kluyveri* Y1164 utilized more glucose than *C. pyralidae* Y1117 and *P. kluyveri* Y1125. The growth inhibition activity, illustrated by the VZI values [6], as the result of yeast growth and secondary metabolite production, i.e., the biopreservation compound concentrations, in the crude was found to be lower for *P. kluyveri* Y1164 than those for *C. pyralidae* Y1117 and *P. kluyveri* Y1125. The biological

stoichiometric results showed an interesting interplay in this regard, whereby the growth model generated for *P. kluyveri* Y1164 demonstrated the need for more dissolved oxygen in comparison to other yeasts. Additionally, less biomass was generated, albeit with more water formation in product metabolism of *P. kluyveri* Y1164, which can explain the VZI variations observed. Therefore, the generated data reported in this study can be useful for system design for biopreservation compound production using GPE or a similar agro-waste medium, depending on the source, for fermentation systems. Additionally, these models (Tables 5 and 6) can be useful to simulate both mass and energy relationships for bioprocess simulation packages currently in development without the need for laboratory experimentation.

Table 5. Catabolism and anabolism equations for biopreservation compound production per unit glucose used by *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 using grape pomace extracts as fermentation medium.

3.4. Bioenergetic Parameters Determination

The combustion equations were used to determine the bioenergetic parameters for each of the biocontrol yeasts—see Table 7.

Table 7. The combustion equations used for the calculation of energy requirements during biochemical conversion of substrate for growth and secondary metabolite production (biopreservatives) by *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 using grape pomace extract as fermentation medium.

Yeast	Combustion Equations
<i>C. pyralidae</i> Y1117	$CH_{1.906}N_{0.149}O_{0.805}S_{0.003}(cell) + 1.475O_2 \rightarrow CO_{2(g)} + 0.95H_2O_{(l)} + 0.0745N_{2(g)} + 0.003 H_2S_{(g)}$
<i>P. kluyveri</i> Y1125	$CH_{1.891}N_{0.132}O_{0.833}S_{0.003}(cell) + 1.055O_2 \rightarrow CO_{2(g)} + 0.942H_2O_{(l)} + 0.066N_{2(g)} + 0.003 H_2S_{(g)}$
<i>P. kluyveri</i> Y1164	$CH_{1.868}N_{0.146}O_{0.698}S_{0.003}(cell) + 1.116O_2 \rightarrow CO_{2(g)} + 0.931H_2O_{(l)} + 0.066N_{2(g)} + 0.003 H_2S_{(g)}$

Thermodynamic parameters as analyzed in a bomb calorimeter, particularly the heat of combustion (ΔH_c^{cell}) for the dried *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 biomass, was determined to be 12.29, 17.98, and 17.09 kJ/g, respectively. Furthermore, the experimental enthalpy of combustion for the three biocontrol yeasts was found to be -471.89 kJ/C-mol for *C. pyralidae* Y1117, -524.35 kJ/C-mol for *P. kluyveri* Y1125, and -464.44 kJ/C-mol for *P. kluyveri* Y1164. The variations in bioenergetics were calculated using the values obtained from the bomb calorimeter and the thermodynamic properties found in the literature and listed in Table 2. Thornton's rule and approach (Equation (7)) was used—a technique that is similar to the approach reported in Akinpelu et al. [11] and Thornton [15].

$$\Delta H_c^o = -107.9 \frac{kJ}{eq} X(eq. \text{ transferred to oxygen during bomb calorimetric combustion}) \quad (7)$$

The key thermodynamic parameters of interest were enthalpy of biomass formation ΔH_f^{cell} , heat of reaction ΔH_{RX}^O , and the entropy changes ΔS_{RX}^O —see Table 8. The heat of formation was observed to be -195.23 kJ C-mol $^{-1}$ (*P. kluyveri* Y1164) $>$ -193.22 kJ C-mol $^{-1}$ (*C. pyralidae* Y1117) $>$ -138.46 kJ C-mol $^{-1}$ (*P. kluyveri* Y1125). Overall, a higher exothermic value translated to higher values for yeast growth during fermentation, which also explains the yield values obtained during the kinetic study by Mewa-Ngongang et al. [6]. Furthermore, the biomass formation was hypothetically spontaneous for the system developed using GPE. Entropy values were determined, i.e., -0.45 , -0.21 , and -0.53 kJ K $^{-1}$ C-mol for *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164, respectively, translating to an entropically driven process. Based on previous studies on bioenergetics, the values obtained for the bioenergetic parameters studied and reported herein are in agreement with what has been reported elsewhere [7,8,11,13].

Table 8. Thermodynamic parameters during biochemical conversion of substrate and secondary metabolite production (biopreservatives) by *C. pyralidae* Y1117, *P. kluyveri* Y1125, and *P. kluyveri* Y1164 using grape pomace extract as fermentation medium at 298.15 K and 1 atm.

Yeast	$\Delta H_f^{cell} (\text{kJ C-mol}^{-1})$	$\Delta H_{RX}^O (\text{kJ C-mol}^{-1})$	$-\Delta G_{RX}^O (\text{kJ C-mol}^{-1})$	$\Delta S_{RX}^O (\text{kJ K}^{-1} \text{C-mol}^{-1})$
<i>C. pyralidae</i> Y1117	−193.22	−5006.75	−5141.07	−0.45
<i>P. kluyveri</i> Y1125	−138.463	−5160.48	−5223.87	−0.21
<i>P. kluyveri</i> Y1164	−195.23	−8283.54	−8441.26	−0.53

4. Conclusions

The stoichiometric models and bioenergetic parameters analyzed in this study do not necessarily indicate the potential of the yeast or the process to produce biopreservatives but illustrate biochemical conversion of substrates needed for growth and production of secondary metabolites. Furthermore, this study does not report on the optimization of biopreservation production, but rather maximizing the consumption of agro-waste material. For an adequate biochemical system design for biopreservative production by non-*Saccharomyces* yeasts, important engineering and biological aspects are always needed. This has been successfully addressed by the outcome of this work, whereby numerous stoichiometric and bioenergetic parameters were determined. The biological stoichiometric models have been effectively developed, which accounted for mass and part of the energy balances required for simulation of industrial-scale production of biopreservatives using cheaply available, renewable agro-waste as raw material. The key parameters presented in this work can be used in prediction of performance as well as the feasibility of metabolic reactions during industrial-scale production of biopreservatives from biocontrol yeasts. Additionally, the model and bioenergetics data reported are only applicable to the yeast strains used in this study. This work is the first to report on biological stoichiometry and bioenergetics during biochemical conversion of substrate and secondary metabolite production (biopreservatives) by non-*Saccharomyces* yeasts using grape pomace extract as fermentation medium. Future studies should be undertaken using other agro-waste or substrate sources and compared to the data generated by this study.

All authors have read and agreed to the published version of the manuscript.

Funding: The financial support was provided by the National Research Foundation (NRF) (Grant 117833), the Agricultural Research Council (ARC) of South Africa, and the Bioresource Engineering Research Group (BioERG).

Institutional Review Board Statement: Not applicable.

Informed Consent Statement: Not applicable as this study did not involve humans.

Acknowledgments: The authors would like to thank the Agricultural Research Council (ARC), the National Research Foundation (NRF), and the Bioresource Engineering Research Group (BioERG), Department of Biotechnology, Cape Peninsula University of Technology, for funding and infrastructure. The authors thank all students, interns, technicians, and research assistants who contributed. The grant holders acknowledge that opinions, findings and conclusions or recommendations expressed in this publication, are those of the authors, and that the NRF accepts no liability whatsoever in this regard. The funding body had no involvement in the following aspects: study design; collection, analysis and interpretation of data; writing of the manuscript; decision to publish the work.

Conflicts of Interest: The authors hereby declare that they have no conflict of interest.
