SUPPLEMENTARY METHODS

Leaf trait variation between canopy points within an individual tree

We assessed the effect of sampling from a single canopy point by collecting a second set of 10 leaves from a different side of the canopy for 32 trees across families and replicates. Differences in leaf area, length, weight and thickness between canopy points within an individual tree were assessed by a two-sample t-test in R v 3.2.1 ('t.test' function; [1]), using individual leaf data (10 leaves / position). To account for multiple testing, a Bonferroni correction was applied to p -values on a trait-by-trait basis. The amount of variance within trees, between canopy points, and between trees was also assessed via a mixed model using the R package 'lme4' v 1.1-12 [2]. Using individual leaf data, a model including tree and position within tree as random effects was implemented.

Little difference was found in leaf trait measurements between canopy points with only three comparisons across all four traits and 32 trees tested significantly different after correction for multiple testing (Table S2). Similarly, variance between individual trees was 3.9 – 6.6 times greater than variance between canopy points within a tree (Table S3), suggesting that most of the variation in traits occurs between rather than within trees.

Comparing Q_{ST} to an empirical F_{ST} distribution

Where large numbers of neutral loci are available, an empirical neutral F_{ST} distribution may be calculated to avoid limitations associated with estimating a distribution of F_{ST} values from a single mean value [3]. An empirical distribution of neutral F_{ST} values was created for the sampled region of *Eucalyptus microcarpa* (Grey box) in this study using existing sequencing data for 418 'neutral' SNPs for 157 samples from the seven original provenance populations [4]. 'Neutral' SNPs were defined as those not significant in four genomic outlier analyses and annotated as synonymous or intergenic only based on *E. grandis* v1.1 annotations within 5,000 bp of the SNP [5]. For Bendigo, the original provenance population could not be located so a large natural stand near the original provenance location was sampled as a representative site. Per locus, unweighted F_{ST} estimates were calculated using the 'MakeDiploidFSTMat' function in the R package 'OutFLANK' v 0.1 [6]. F_{ST} estimates weighted for sample size can produce estimates with slight negative values. This unweighted method was chosen to ensure only positive F_{ST} estimates, making results comparable to Q_{ST} and χ^2 distributions which cannot have

negative values. Trait Q_{ST} values were considered significantly greater than neutral F_{ST} if the lower bound of the Q_{ST} SE was greater than the upper 5% bound of empirical F_{ST} values, i.e. $Q_{ST} > F_{ST}$, even when considering error. As empirical distributions may be influenced by sampling bias in the SNPs included, results were also compared to a theoretical χ^2 distribution (see main article).

Q_{ST} estimates for tree height, leaf area, leaf length and leaf weight exceeded neutral F_{ST} , suggesting these traits are potentially under divergent selection (Figure S1). Based on 418 ‘neutral’ SNPs from the original provenance populations, mean neutral F_{ST} was 0.033, with an upper 5% bound of 0.069 (Figure S1). For tree height, leaf area, leaf length and leaf weight, Q_{ST} was greater than the empirical 5% neutral F_{ST} cut-off, even when accounting for one SE.

Table S1. Definitions for climate variables used in climate association analysis of quantitative traits and putatively adaptive SNPs in *Eucalyptus microcarpa* (Grey box). All data are environment (gridded) layers with 0.01 degree (~1 km) resolution.

Climate variable	Variable Definition ¹
<u>Aridity (ratio)</u>	
Mean annual aridity index	Monthly ratio precipitation to potential evaporation (pan, free-water surface)
Maximum month aridity index	Monthly ratio precipitation to potential evaporation (pan, free-water surface)
<u>Precipitation (mm)</u>	
Annual Precipitation (Bio12)	Sum of all 12 monthly precipitation estimates. Centered on 1990
Average winter (Jun, Jul, Aug) precipitation	Based on 109 years of data
Average summer (Dec, Jan, Feb) precipitation	Based on 109 years of data
Precipitation of Driest Period (Bio14)	The precipitation of the driest period. Centered on 1990
Precipitation of Wettest Period (Bio13)	The precipitation of the wettest period. Centered on 1990
<u>Temperature (°C)</u>	
Annual Mean Temperature (Bio01)	Mean weekly mean temperatures (weekly mean = mean of the weekly max. and min. temperatures over the year). Centered on 1990.
Max month absolute mean max temperature	The monthly mean absolute maximum temperature derived from the hottest day of each month over 50-years (1955 to 2005) of 5km gridded daily climate.
Max Temperature of Warmest Period (Bio05)	Highest weekly maximum temperature in all weeks of the year. Centered on 1990

DBH = Diameter at breast height; SLA = Specific Leaf Area

Adj. r^2 = adjusted r^2 of linear model; Lat. = Latitude; Long. = Longitude; Env. = Environment; Abs. = absolute

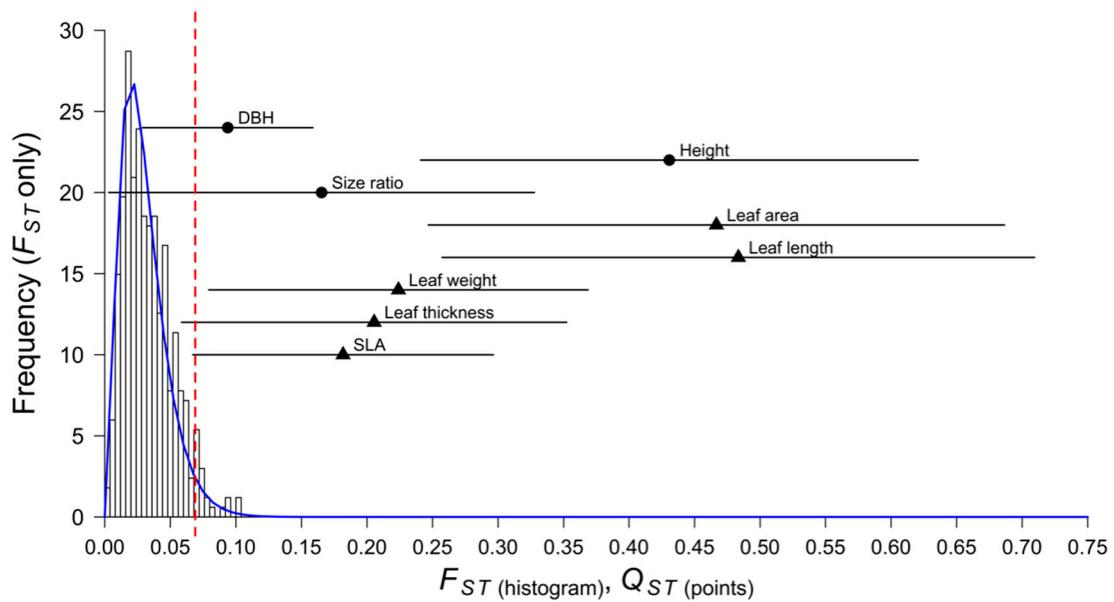

Figure S1 Empirical per locus ‘neutral’ F_{ST} distribution (bar plot) for *Eucalyptus microcarpa* (Grey box) and Q_{ST} estimates (points; circles = growth traits, triangles = leaf traits, lines = one standard error). F_{ST} calculated from 418 ‘neutral’ SNPs using 157 samples from the seven original natural provenance populations. Dashed red line = 5% upper limit of per locus F_{ST} estimates (empirical 95% cut-off). Blue line = χ^2 distribution based on 3.3 degrees of freedom (mean F_{ST} ‘neutral’ SNPs = 0.033). Leaf density not plotted ($Q_{ST} = 1 +/ - 0$ (SE)).

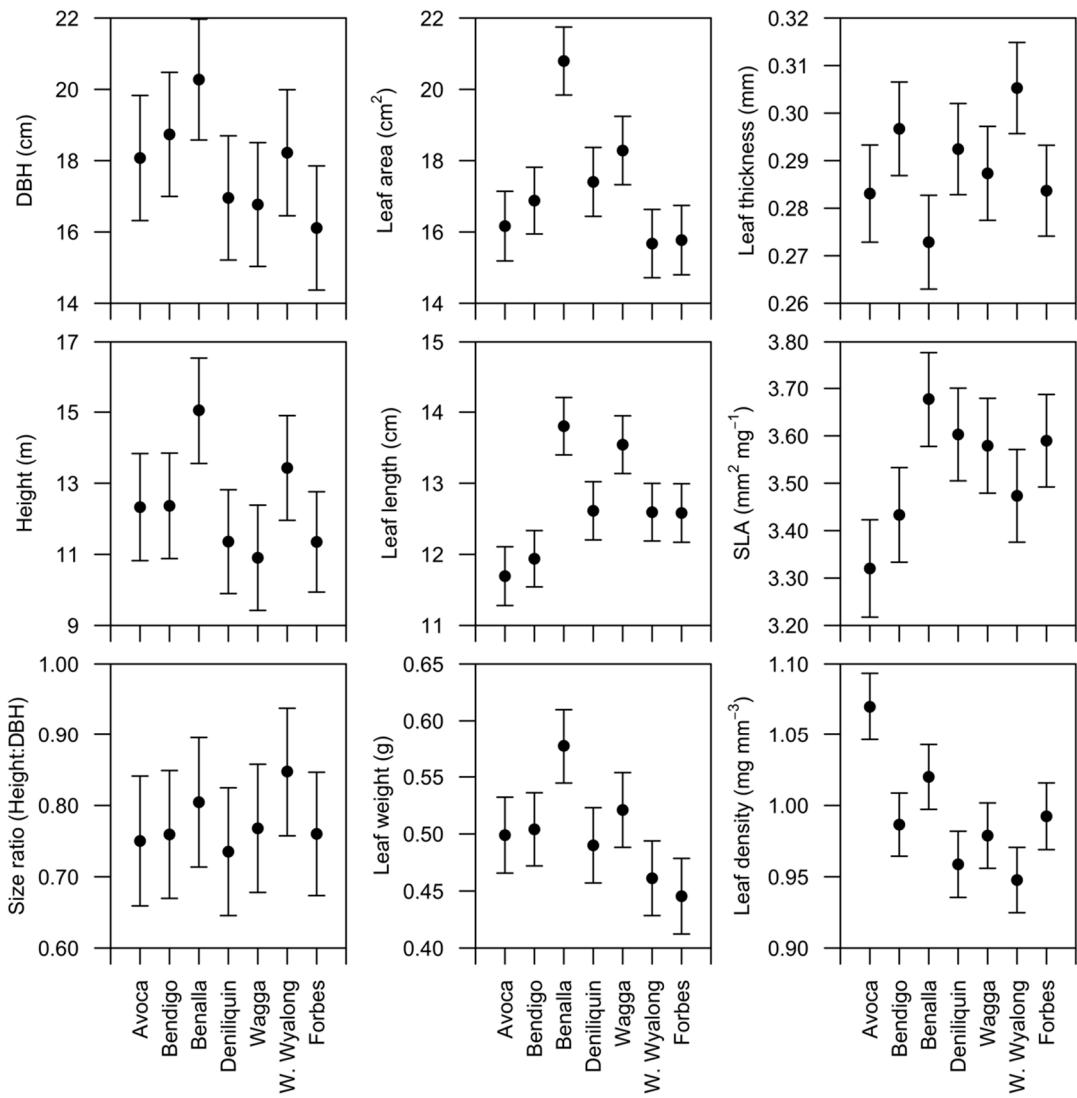

Figure S2 Provenance level, Best Linear Unbiased Estimates (BLUEs) for nine quantitative traits measured in *Eucalyptus microcarpa* (Grey box). Provenances ordered from south (left) to north (right). Error bars = 95% confidence interval. Note different scales on y-axes.
