Abstract: Understanding terrestrial water storage (TWS) dynamics and associated drivers (e.g., climate variability, vegetation change, and human activities) across climate zones is essential for designing water resources management strategies in a changing environment. This study estimated TWS anomalies (TWSAs) based on the corrected Gravity Recovery and Climate Experiment (GRACE) gravity satellite data and derived driving factors for 214 watersheds across six climate zones in China. We evaluated the long-term trends and stationarities of TWSAs from 2004 to 2014 using the Mann–Kendall trend test and Augmented Dickey–Fuller stationarity test, respectively, and identified the key driving factors for TWSAs using the partial correlation analysis. The results indicated that increased TWSAs were observed in watersheds in tropical and subtropical climate zones, while decreased TWSAs were found in alpine and warm temperate watersheds. For tropical watersheds, increases in TWS were caused by increasing water conservation capacity as a result of large-scale plantations and the implementation of natural forest protection programs. For subtropical watersheds, TWS increments were driven by increasing precipitation and forestation. The decreasing tendency in TWS in warm temperate watersheds was related to intensive human activities. In the cold temperate zone, increased precipitation and soil moisture resulting from accelerated and advanced melting of frozen soils outweigh the above-ground evapotranspiration losses, which consequently led to the upward tendency in TWS in some watersheds (e.g., Xiaoxing’anling mountains). In the alpine climate zone, significant declines in TWS were caused by declined precipitation and soil moisture and increased evapotranspiration and glacier retreats due to global warming, as well as increased agriculture activities. These findings can provide critical scientific evidence and guidance for policymakers to design adaptive strategies and plans for watershed-scale water resources and forest management in different climate zones.

Keywords: terrestrial water storage; climate zones; forest change; climate variability; human activities; GRACE satellite

1. Introduction

Terrestrial water storage (TWS) including surface water, groundwater, lakes, snow, and ice has been viewed as an important indicator for assessing water resources [1]. However, the estimations of TWS at larger spatial scales are rather challenging. The high-cost in situ measurements can provide robust estimations of TWS but are only available for relatively small watersheds. Early satellite observations can be used to estimate surface water and shallow soil water but with a significant limitation in estimating deep soil moisture and

groundwater. The Gravity Recovery and Climate Experiment (GRACE) satellite launched in 2002 by the National Aeronautics and Space Administration (NASA) and German Aerospace Center (DLR) has been identified as an effective tool to measure the mass changes within the Earth system. Although the GRACE satellite cannot directly generate the estimations of the absolute values of TWS, GRACE data can be further proceeded to retrieve the TWS anomalies (TWSAs). The positive and negative values of TWSAs can be used to indicate water surplus and water deficits, respectively [2]. Various studies have validated the availability and accuracy of GRACE data over a large scale [3–6]. The estimations of TWSAs by GRACE have greatly improved our understanding of spatial and temporal variations of TWS changes at a large scale. As indicated by GRACE retrievals, significant changes in TWS have been observed worldwide, where both significant decreasing and increasing trends in TWS have been reported in different regions. For example, TWS significantly decreased by 0.42 ± 0.12 cm/year in the Tianshan Mountains in Northwest China from 2003 to 2013 [7]. Similar declines in TWS were also observed in Amazon and Central Asia [8,9]. Contrarily, there were significant increases in TWS in North America, even though there were extreme drought events from 1999 to 2005 [10]. Those changes in TWS will inevitably threaten watershed and regional water supply and flood control [11]. Therefore, understanding TWS changes and associated regional differences is essential for future water resource management.

Climate variability and change (e.g., global warming, El Niño, drought, and heat-waves), vegetation change (e.g., deforestation, reforestation, and land-use change), and extensive anthropogenic activities (e.g., groundwater exploitation, irrigation, mining, and dam construction) can considerably affect TWS and the availability of water resources [12–15]. Climate variability is the major driver for TWS variations, which can directly affect the water cycle by influencing precipitation and evapotranspiration (*ET*), resulting in variations in TWS [16]. TWS variations associated with climate variability are often limited within a natural range, which ensures a stable and predictable water supply for human beings [17]. However, climate change, vegetation change, and human disturbances have greatly altered TWS and intensified its variability in recent years [18–20], especially in areas that are sensitive to climate change (e.g., alpine regions) or experience frequent groundwater extractions (e.g., arid and semiarid regions) [21,22]. For example, global warming-induced glacial melting has been found to significantly decrease TWS in the Greenland Ice Sheet [23]. Increasing trends in drought frequency and severity due to climate change have posed substantial stress on TWS in the Yangtze, Pearl, Huaihe, Southeast, and Songhua River Basins of China [24,25]. In addition, vegetation change either due to climate change or human activities frequently alters the water cycle. The general perception is that deforestation (e.g., harvesting, urbanization, wildfire, and insect infestation) can significantly increase annual runoff and alter peak flows [26–31], while forestation can decrease annual runoff and reduce peak flows [32–35]. Furthermore, human activities such as dam construction have often been found to affect TWS by increasing surface water bodies and altering natural flow regimes [17,36]. Intensive human activities can also affect TWS downstream. For instance, flow reductions were observed downstream of the Shiyang River Basin [37], resulting from large-scale irrigation activities upstream. Obviously, it is of great necessity to study how these drivers (climate, vegetation, and human activities) affect TWS for maintaining sustainable water resources.

Variations in TWS actually differ among regions or watersheds due to their differences in topography, climate, vegetation, and geology as well as in human activities and land use change. Therefore, examining the variations in TWS and associated drivers must be placed within an environmental context to understand the mechanism for TWS changes and devising watershed or region-specific strategies for water resource management in a changing environment. China covers a large span of climate gradients, which can be classified into six climate zones. Each climate zone differs in climate variability and change, vegetation change, and human activities, where watershed TWS may demonstrate different change patterns and driving mechanisms. However, previous studies have generally

assessed the TWS dynamics in single watersheds [38–40]. There is still a lack of studies investigating the changes in watershed TWS and associated driving mechanisms (e.g., climate, vegetation change, and human activities) across climate gradients, which impedes the design of water resource management and forest restoration to adapt TWS variations in watersheds across climate zones. To address these issues, this study aims to detect the change trends and stationarities of TWS and identify the relationships between TWS with its driving factors in watersheds located in six climate zones in China. The findings from this study could provide critical information to design adaptive strategies and plans for watershed-scale water resources and forest management in different climate zones.

2. Materials and Methods

2.1. Study Area

China ($3^{\circ}51' \text{ N}$ – $53^{\circ}33' \text{ N}$, $73^{\circ}33' \text{ E}$ – $135^{\circ}05' \text{ E}$) has complex river networks, which can be classified into 214 third-order watersheds with areas ranging from 24.89 to $7.92 \times 10^5 \text{ km}^2$ according to the watershed classification criteria provided by the Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences (CAS). Detailed information about the watershed size and climate conditions for 214 watersheds is listed in Table A1. There are six climate zones in China, including tropical monsoon (T), subtropical monsoon (ST), warm temperate (W), mild temperate (M), cold temperate (C), and alpine climate (A) zones (Figure 1). Given that only four watersheds are located in the cold temperate zone, we combined the mild and cold temperate zones into the ‘mild-cold temperate zone (MC)’ in the analysis. China is characterized by distinct spatial patterns of temperature and precipitation where annual precipitation and mean temperature increase from the north (e.g., 238.17 mm and -11° C in the Chip Chap River watershed) to the south (e.g., 2000.36 mm and 23° C in Hainan Island) (Table A1 and Figure A1). China also covers a wide variety of vegetation types including shrubs, grasses, broadleaf forests, coniferous forests, and tropical forests (Figure A2). Watersheds in tropical and subtropical climate zones are mainly dominated by forests while those in warm temperate, mild-cold temperate, and alpine climate zones are mostly covered by grass (Figure 2 and Table 1). The average forest coverage for watersheds in tropical, subtropical, warm temperate, mild-cold temperate, and alpine climate zones are 73.31, 60.88, 10.77, 26.13, and 1.36%, respectively. Human disturbances (e.g., industry, agriculture, hydropower development, and urbanization) are widespread across China, especially in southern, central, and eastern China. Water shortage is a common problem in most cities with low water resource capacity for economic development in northern China, which rely on the South-to-North Water Diversion Project to sustain water use by growing populations [41].

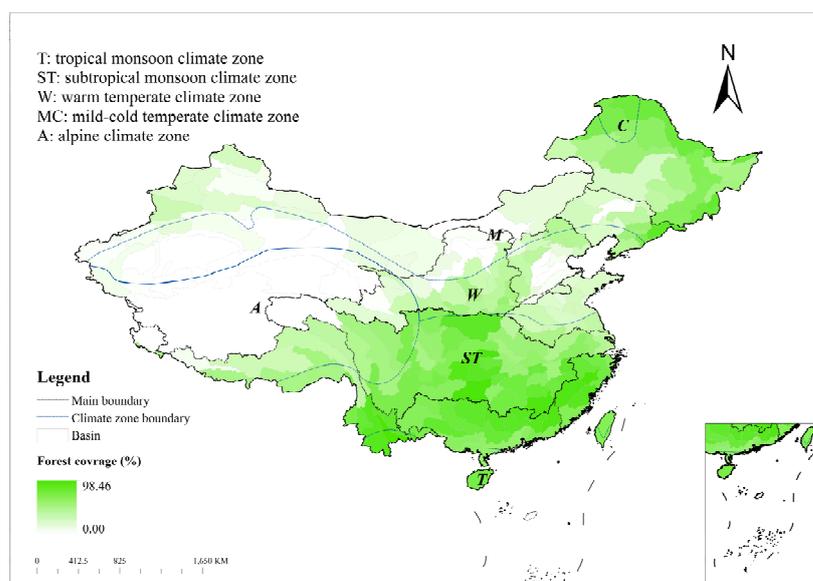

Figure 2. The forest coverage in 214 watersheds across six climate zones in China.

Table 1. The vegetation coverage across six climate zones in China.

Climate Zone	Area (km ²)	<i>P</i> (mm)	<i>T</i> _{ave} (°C)	FC (%)	SC (%)	GC (%)
All (<i>n</i> = 214)	9.84 × 10 ⁶	862.15	10.40	36.31	0.14	21.73
Tropical monsoon (<i>n</i> = 11)	3.62 × 10 ⁵	1445.57	18.21	73.31	0.01	4.22
Subtropical monsoon (<i>n</i> = 88)	30.23 × 10 ⁵	1296.02	14.85	60.88	0.03	6.44
Warm temperate (<i>n</i> = 50)	16.30 × 10 ⁵	541.54	10.32	10.77	0.30	25.89
Mild-cold temperate (<i>n</i> = 39)	20.69 × 10 ⁵	483.49	4.07	26.13	0.29	38.93
Alpine climate (<i>n</i> = 26)	27.62 × 10 ⁵	331.43	1.68	1.36	0.13	47.16

Note: *P*, *T*_{ave}, FC, SC, GC denote precipitation, average temperature, forest coverage, shrub coverage, and grassland coverage, respectively.

2.2. Data

The GRACE Level-2 products provided by the Centre for Space Research (CSR) at the University of Texas (UTCSR: <http://www.csr.utexas.edu/datasets/>) (accessed on 1 December 2020) were used to extract GRACE data covering China from 2004 to 2014 in this study. The existing *C*₂₀ term, an index to express gravitational variations, was replaced by the *C*₂₀ term obtained by Satellite Laser Ranging (SLR) to improve the accuracy of the estimations [42,43]. Given that the correlations between spherical harmonic coefficients of different orders in the GRACE products would lead to bandings in images, decorrelation was applied first to remove north–south stripes. Then, the Gaussian smoothing filter was used to reduce errors from high orders. Finally, we applied the method recommended by Wahr et al., 1998 to generate the 0.25° × 0.25° TWSAs images, where TWSAs in watersheds across six climate zones in China from 2004 to 2014 can be derived to perform the following analyses [44]. We applied high-frequency filtering and de-stripping algorithms to reduce the noise level of GRACE data, which have been proven to be effective but would weaken the effective signal of the model [45–47]. The signal in the target region may leak into the surrounding areas and cause amplitude damping in the region (leakage-out). The signal from the surrounding areas may also leak into the target region (leakage-in). To address this issue, we used the signal leakage algorithm and applied the GRACE Matlab Toolbox (GRAMAT) to mitigate the effect of signal leakage. The toolbox was developed on the MacOSX operating systems with the Matlab software (version R2014a) by Feng Wei (Wuhan, China) [47]. Then, we applied the scaling method to downscale the resolution, which optimizes the basin shape descriptions. Existing studies [47–49] have indicated this method is suitable for retrieving TWS for small basins.

Monthly climate data with a spatial resolution of 0.5° , including precipitation, evapotranspiration, and mean temperature, were collected from Chinese Surface Climate Information of the National Meteorological Information Center (<http://www.nmic.cn/>) (accessed on 1 February 2021). Effective precipitation (PE), which refers to the precipitation that is available for the generation of surface water, was calculated as the difference between precipitation (P) and evapotranspiration (ET) by Equation (1) [50].

$$PE = P - ET \quad (1)$$

Three types of vegetation data including the leaf area index (LAI), normalized difference vegetation index (NDVI), and vegetation fraction coverage (VFC) were used to describe vegetation conditions. LAI data were derived from the Global Land Surface Satellite LAI (GLASS LAI) product provided by the National Earth System Science Data Center (<http://www.geodata.cn>) (accessed on 5 February 2021), with a spatial resolution of 0.05° . NDVI was obtained from the Global Inventory Modelling and Mapping Studies (GIMMS) NDVI 3 g dataset at a temporal resolution of 15 days and a spatial resolution of $1/12^\circ$ (<http://poles.tpdc.ac.cn/en/data/9775f2b4-7370-4e5e-a537-3482c9a83d88/>) (accessed on 5 February 2021). VFC was calculated based on NDVI (Equation (2)).

$$VFC = (NDVI - NDVI_{min}) / (NDVI_{max} - NDVI_{min}) \quad (2)$$

To describe watershed characteristics, we also used soil moisture and land cover data. The soil moisture data were derived from the Global Land Data Assimilation System (GLDAS) dataset with a spatial resolution of 500 m (<https://ldas.gsfc.nasa.gov/gldas>) (accessed on 10 February 2021). Land cover data were derived from the MODIS Land Cover Type Product (MCD12Q1) with a spatial resolution of 500 m (<https://ladsweb.modaps.eosdis.nasa.gov/>) (accessed on 10 February 2021).

Human activities data were derived from the China National Bureau of Statistics (<http://www.stats.gov.cn/>) (accessed on 1 March 2021) and WorldPop (<https://www.worldpop.org/>) (accessed on 5 March 2021). The former dataset provided human activities data of each province including the Gross Domestic Product (GDP), per capita GDP, irrigated area, water consumption for industrial, agricultural, and domestic activities, and total water consumption, while the latter had annual population density data with a spatial resolution of 1 km. To calculate watershed-scale human activity data, we firstly derived gridded-based population density at the watershed and province scale from WorldPop, respectively, to calculate the population density ratio (p_i) for each watershed (Equation (3)). Then, we calculated human activity data for each watershed (A_i) according to human activity data at the province scale (A) and p_i (Equation (4)).

$$p_i = PD_i / PD \quad (3)$$

$$A_i = p_i \times A \quad (4)$$

where p_i , PD_i , PD , A_i , and A denote the population density ratio, population density at the watershed scale, population density at the province scale, human activity data at the watershed scale, and human activity data at the province scale, respectively.

2.3. Methods

This study was designed to identify TWS dynamics and associated driving factors in watersheds across six climate zones in China (Figure 3). Firstly, the potential driving factors for watershed TWS were classified into three types: Climate, watershed characteristics, and human activities, which were widely used in existing studies [51–59]. The selected climate factors include annual precipitation (P), effective precipitation (PE), evapotranspiration (ET), and annual mean temperature (T_{ave}). Soil moisture (SM) and vegetation indices including LAI, NDVI, and VFC were selected to represent watershed characteristics for TWS variations, while factors such as water use by agriculture, industry, and domestic

activities, population density, and GDP were selected to express human influences. Detailed information on drivers can be found in Table 2.

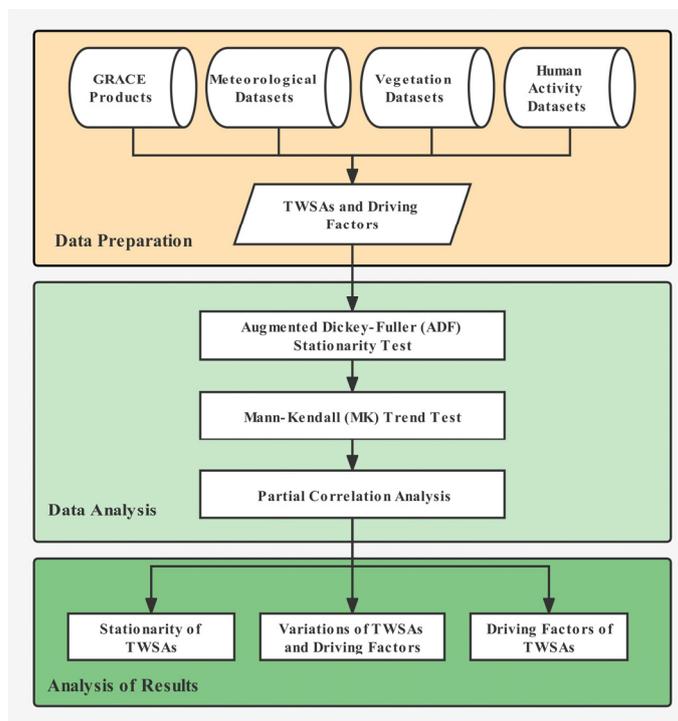

Figure 3. Research design.

Table 2. The summary of driving factors for watershed TWS.

Type of Factors	Index	Symbol	Unit
Climate	Precipitation	<i>P</i>	mm
	Effective precipitation	<i>PE</i>	mm
	Evapotranspiration	<i>ET</i>	mm
	Temperature	<i>T_{ave}</i>	°C
Watershed characteristics	Leaf area index	LAI	m ² /m ²
	Normalized difference vegetation index	NDVI	-
	Vegetation fraction coverage	VFC	%
	Soil moisture	SM	%
Human activities	Industrial water use	IND	mm
	Agricultural water use	AGR	mm
	Domestic water use	DW	mm
	Total water use	WT	mm
	Irrigated area	IRR	10 ³ hm
	Population density	PD	persons/km ²
	Gross domestic product	GDP	RMB
Per capita GDP	PERGDP	RMB	

The augmented unit root test (ADF test) proposed by Dickey and Fuller was then used to test the stationarity of each time series of data, which can indicate the inter-annual variations of TWS [60,61]. In the ADF test, the stationarity is evaluated based on the absolute value of the characteristic roots [60,62]. If the *t* statistic is less than that of a given percentage level (e.g., 10% level) and the probability is greater than 0.10, the time series is non-stationary [63]. The non-parametric Mann–Kendall (MK) trend test was applied to detect the statistical significance of trends in data series, e.g., TWSAs for each study watershed from 2004 to 2014 with a significance level of 0.05 [64–66]. The partial correlation

analysis was finally adopted in this study to detect the correlations between TWSAs and driving factors at a statistically significant 0.05 level, which can indicate the key factors for TWS variations, as well as the associated driving mechanisms [51].

3. Results

3.1. TWSAs and Driving Factors: Trend and Stationarity

3.1.1. Trends and Stationarities of TWSAs

As suggested by ADF and MK tests (Tables 3 and 4), TWSAs for 214 watersheds from 2004 to 2014 are non-stationary ($t = -2.59$ and $Prob. > 0.10$) with a significant downward trend ($Z = -3.62$ and $p < 0.05$). Although the time series of TWSAs are non-stationary in watersheds from all climate zones, the change patterns of TWSAs differ among climate zones. From 2004 to 2014, there are significant increasing trends ($p < 0.05$) in TWSAs in tropical and subtropical watersheds, and significant decreases in TWSAs ($p < 0.05$) in warm temperate and alpine watersheds. An insignificant trend is detected in watersheds from the mild-cold temperate zone.

Table 3. Results of trends in TWSAs from 2004 to 2014.

Climate Zone	MK Test		
	Z	tau Value	p Value
All ($n = 214$)	-3.62^*	-0.05	0.000
Tropical monsoon zone ($n = 11$)	3.42^{**}	0.18	0.000
Subtropical monsoon zone ($n = 88$)	10.61^{**}	0.23	0.000
Warm temperate zone ($n = 50$)	-20.74^{**}	-0.59	0.000
Alpine climate zone ($n = 26$)	-6.16^{**}	-0.24	0.000
Mild-cold temperate zone ($n = 39$)	1.32	0.04	0.187

Note: $^{**} \alpha = 0.05$, $^* \alpha = 0.10$.

Table 4. Results of stationarity tests in TWSAs.

Climate Zone	Augmented Dicken-Fuller Test Statistic					Stationary
	t-Statistic	1% Level	5% Level	10% Level	Prob. *	
All ($n = 214$)	-2.59	-4.42	-3.26	-3.26	0.13	No
Tropical monsoon zone ($n = 11$)	-2.59	-4.42	-3.26	-2.77	0.13	No
Subtropical monsoon zone ($n = 88$)	-0.18	-4.42	-3.26	-2.77	0.35	No
Warm temperate zone ($n = 50$)	-1.35	-4.30	-3.21	-2.75	0.56	No
Mild-cold temperate zone ($n = 39$)	-1.74	-4.30	-3.21	-2.75	0.38	No
Alpine climate zone ($n = 26$)	-1.16	-4.30	-3.21	-2.75	0.65	No

Note: $^* \alpha = 0.10$.

3.1.2. Trends of Driving Factors

Figure 4 exhibits the results of trend tests for driving factors from 2004 to 2014. Significant increasing trends are detected in NDVI, GDP, PERGDP, WT, and IRR ($p < 0.05$) for all watersheds. Specifically, ET, LAI, NDVI, VFC, IND, GDP, PERGDP, IRR, and PD significantly increase in tropical watersheds. For subtropical watersheds, there are significant increments in ten driving factors (i.e., P, PE, ET, T_{ave} , LAI, NDVI, VFC, DW, GDP, and PERGDP). Significant increments are found in the AGR, WT, GDP, PERGDP, and IRR in watersheds in the mild-cold temperate climate zone. Similarly, significant upward trends are detected in AGR, GDP, PERGDP, and IRR in watersheds in the alpine climate zone. Additionally, a significant decreasing trend is observed in soil moisture (SM), while significant increasing trends are tested in GDP and PERGDP in the warm temperate watersheds.

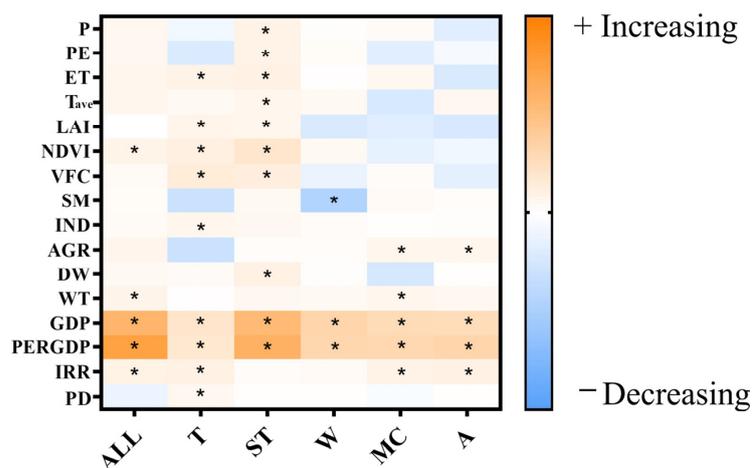

Figure 4. Trend tests of driving factors from 2004 to 2014. * Significant at $\alpha = 0.05$. T, ST, W, MC, and A denote tropical monsoon, subtropical monsoon, warm temperate, mild-cold temperate, and alpine climate zones, respectively.

3.2. Spatial Variations of TWSAs

The spatial pattern of trends in TWS is distinct across climate zones. Significant upward ($p < 0.05$) trends in TWSAs mostly appear in watersheds located in the tropical monsoon, subtropical monsoon, and northern alpine climate zones, while significant downward trends of TWSAs are often found in watersheds in the warm temperate, southern alpine, and western mild-cold temperate climate zones (Figure 5).

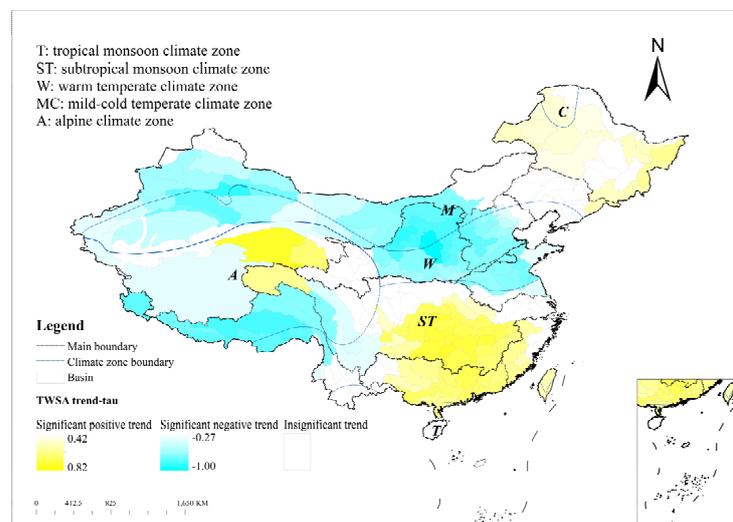

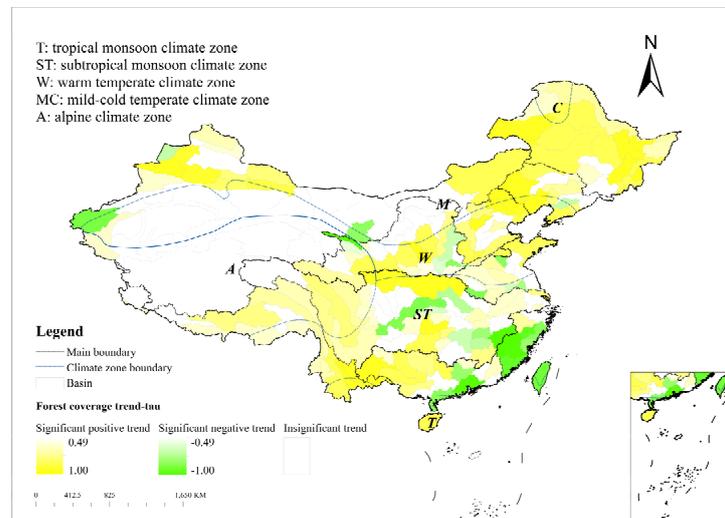

Figure 5. TWSAs trends from 2004 to 2014 in 214 watersheds in China ($p < 0.05$).

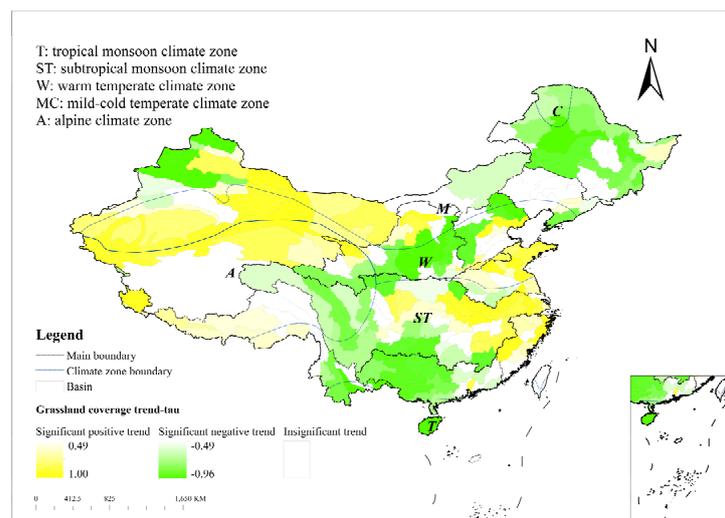

3.3. Spatial Variations of Vegetation Change

Changes in forest and grassland are widespread from 2004 to 2014 in China. According to Figure 6a, significant upward trends ($p < 0.05$) in forest coverage are mainly found in tropical, western subtropical, central warm temperate, and eastern mild-cold temperate watersheds, while significant declines ($p < 0.05$) are found in watersheds located in the eastern subtropical climate zones. Grassland coverage shows significant and rising tendencies ($p < 0.05$) in watersheds located in the western warm or mild temperate (e.g., Tarim Basin), northern alpine, and the eastern subtropical climate zones, whereas significant and decreasing tendencies ($p < 0.05$) are shown in the eastern alpine (e.g., Qaidam Basin and headwater sources of the Yangtze and Yellow Rivers), southwestern subtropical, central warm temperate (particularly the Loess Plateau), and the cold temperate climate zones

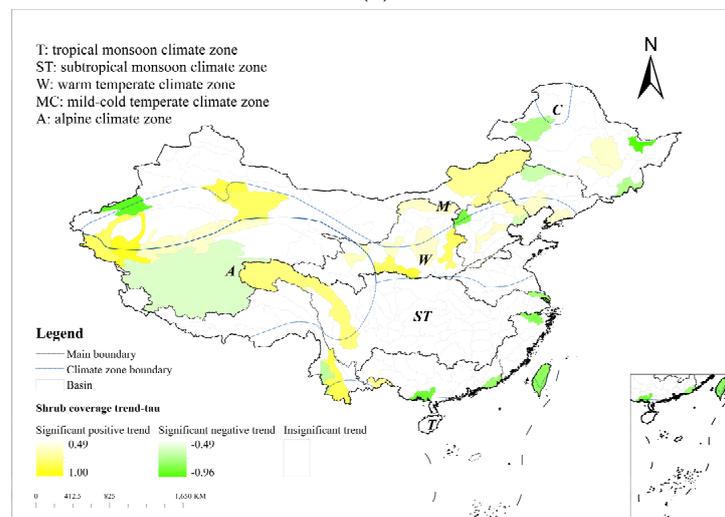

(Figure 6b). Changes in shrubland were generally limited across six climate zones without a distinct pattern (Figure 6c).

(b)

(c)

Figure 6. (a) Forest coverage trends from 2004 to 2014 in 214 watersheds in China ($p < 0.05$); (b) grassland

coverage trends from 2004 to 2014 in 214 watersheds in China ($p < 0.05$); (c) shrub coverage trends from 2004 to 2014 in 214 watersheds in China ($p < 0.05$).

3.4. Key Driving Factors for TWSAs in Different Climate Zones

Climate, watershed characteristics, and human activities can significantly affect TWSAs (Figure 7). As suggested by partial correlation analysis, for 214 watersheds in China, significant positive correlations are observed between TWSAs and P , PE , $NDVI$, and SM , whereas significant negative correlations are found between TWSAs and ET , T_{ave} , IRR , AGR , DW , and WT ($p < 0.05$). Watersheds from each climate zone feature different key driving factors for TWSAs. In tropical monsoon watersheds, significant positive relationships are observed between TWSAs and P , $NDVI$, and SM while significant negative relationships between TWSAs and ET , T_{ave} , and WT are identified. In subtropical watersheds, TWSAs significantly increase with increasing P , PE , $NDVI$, and SM , but decrease with increasing ET , T_{ave} , AGR , and WT . In warm temperate watersheds, TWSAs are positively correlated with P , LAI , $NDVI$, and SM , but negatively correlated with ET , T_{ave} , and human activities (i.e., IRR , IND , AGR , WT , GDP , and $PERGDP$). For watersheds in the mild-cold temperate zone, there are significant and positive relationships between TWSAs and P , PE , $NDVI$, and SM but significant and negative relationships between TWSAs and ET , T_{ave} , LAI , VFC , IND , AGR , WT , and GDP . In addition, TWSAs are positively related to P , PE , $NDVI$, and SM , but negatively correlated with ET , T_{ave} , IRR , AGR , and WT in alpine watersheds.

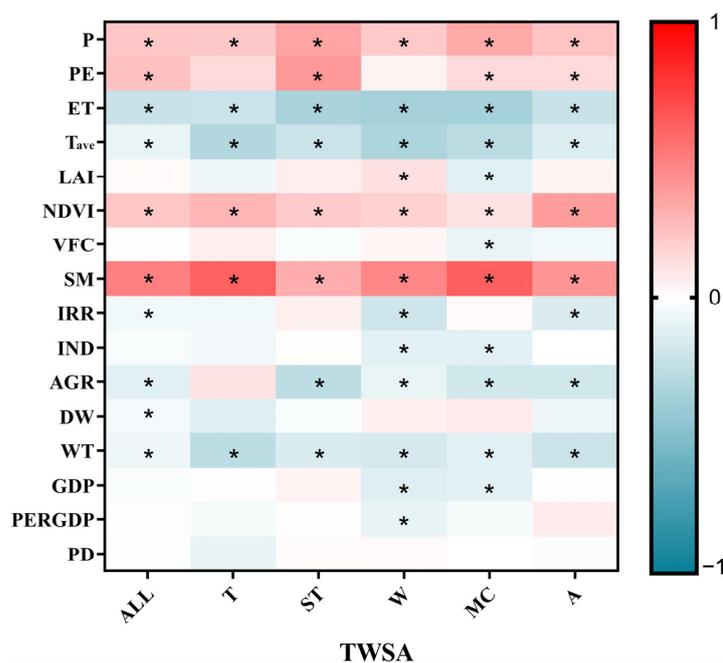

Figure 7. The partial correlations between TWSAs and their driving factors. T, ST, W, MC, and A represent tropical monsoon, subtropical monsoon, warm temperate, mild-cold temperate, and alpine climate zones, respectively. (* Significant at $\alpha = 0.05$).

4. Discussion

4.1. The Dynamics of Terrestrial Water Storage and Their Driving Factors across Climate Zones

Our study clearly indicates that TWS in China was non-stationary and significantly changed (Tables 3 and 4 and Figure 5) by climate variability, vegetation change, and anthropogenic activities from 2004 to 2014 (Figures 7 and A3–A5). Overall, TWSAs show significant downward trends mostly in watersheds in warm temperate, southern alpine, and western mild-cold temperate climate zones during the study period (Figure 5), mainly resulting from intense human activities (i.e., changes in WT and IRR), while significant upward ($p < 0.05$) trends in TWSAs generally appear in watersheds from tropical mon-

soon, subtropical monsoon, and northern alpine climate zones possibly due to increased precipitation and forest coverage (Figure 6a). As suggested by Figures 4 and A4b, NDVI has a significant increasing trend in China as a result of a series of vegetation restoration projects (e.g., the Grain for Grain Program and the Natural Forest Protection Program) since the 1990s, which could improve the water conservation capacity to some extent and may partly contribute to increasing TWSAs in watersheds covered by mature forest stands and well-established vegetation (Figures 6a and 7) [67]. However, the positive impact of vegetation change on TWS can be offset by human activities, which can influence water storage immediately. Fast-growing demands for total water use (WT) and irrigation (IRR) have greatly aggravated water storage deficits (Figures 4, 7 and A5d,e), especially in semi-arid and arid watersheds, resulting in significant declines in TWSAs during the study period [68–70]. For example, Wang et al. [68] found that strongly decreasing trends occurred in surface water and TWS in China from 1989 to 2016.

Nevertheless, TWS dynamics and associated driving factors vary among watersheds from different climate zones. In tropical watersheds, vegetation and climate play important roles in modulating TWS, where P , ET , T_{ave} , $NDVI$, SM , and WT are identified as significant drivers for TWS variations (Figure 7). However, only ET and forest coverage have significant upward trends in tropical watersheds (Figures 4, 6a and A3c), which could be the determinant for the increased TWSAs during the study period. As is known, well-established vegetation covers often play an important role in regulating streamflow, soil moisture, and water retention capacities in ecosystems, which serve as the crucial link between below-ground and above-ground ecohydrological processes [71]. On the one hand, vegetation can increase recharges for groundwater, baseflow, and soil moisture by various hydrological processes such as interception and soil infiltration [72], which is favorable for below-ground TWS. On the other hand, vegetation growth is associated with increased ET , which would decrease surface and total streamflow [31], and thus decrease TWSAs (Figure 7). Given that tropical natural forests often have greater water retention capacities with complex forest structures, which are beneficial for maintaining water resources [73,74], a significant water surplus is expected in tropical watersheds once the increments in below-ground water storage outweigh the above-ground ET losses by forest growth.

In subtropical watersheds, climate and vegetation are also the main contributors to the increased TWS over the study period. A large number of subtropical watersheds have significantly increased forest coverage and NDVI (Figures 6a and A4b) due to afforestation and reforestation. The well-established forest stands can intercept rainfall through the canopy, reducing the raindrop velocity and protecting surface soil [75]. Moreover, forests are characterized by deep rooting systems that can promote infiltration, recharge baseflow and groundwater, and mitigate soil erosion, which could eventually increase TWSAs. In addition, significant increments in precipitation and effective precipitation also contribute to TWSA increases (Figures 4 and 7) in these subtropical watersheds, although rising ET and T_{ave} may offset the increase in TWS caused by vegetation and precipitation increase (Figures 4, 7 and A3c,d). Besides, although TWSAs are significantly related to WT and AGR in a negative way (Figure 7), these two anthropogenic drivers show insignificant changes during the study period, and thus yield limited contributions to TWS in subtropical watersheds.

The decreasing tendency in TWS over the study period is widespread in warm temperate watersheds (Figure 5), which largely corresponds to significant declines in soil moisture (Figure 4), especially in watersheds located in the North China Plain and the northern Loess Plateau (Figure A4d). In addition, intensive human activities with fast-growing water use by agriculture (e.g., AGR and IRR) and urban development (e.g., IND , DW , and WT) (Figures 7 and A5) are also the main contributors to the decreased TWS in warm temperate watersheds. Moreover, the declines in TWS can be aggravated by vegetation loss (e.g., the clearance of grass and forest) as a result of settlement development and agricultural expansion, especially in some watersheds in the North China Plain [76] where grassland degradation (Figure 6b) due to urbanization, agricultural expansion, and groundwater

exploitation (Figure A5) is widespread. The negative impact of human activities on TWS can sometimes even override the positive effect of precipitation and vegetation on TWS. For example, increasing precipitation and vegetation in watersheds in the Loess Plateau would potentially increase TWS (Figures A3a and A4a–c), while intense human activities offset the increments, eventually leading to a significant decline in TWS (Figures 5, 7 and A5). These indicate that most watersheds in the warm temperature climate zone have been confronted with growing water shortages due to excessive human activities over the study period, where water supply could be under much greater stress in the future with reduced precipitation under climate change.

In the alpine climate zone, significant declines in TWS are detected in watersheds in the southern and southeastern Qinghai–Tibet Plateau, while increasing TWS are observed in watersheds in the Qaidam Basin and headwater sources of the Yangtze River. Watersheds in the alpine climate zone are very sensitive to climate change given their large area of frozen soils, permanent snows, and glaciers. TWS variations in these watersheds are mainly controlled by climate and climate-induced vegetation change, such as agriculture activities, grazing, and cultivation (Figure A3a–d). For example, in the past 20–30 years, 38.8% of the grassland and nearly 50% of broad-leaf forest in the Qinghai–Tibet plateau were under degradation mainly due to climate change and grazing, which inevitably reduced TWS in this area [77,78]. Although precipitation significantly decreased over the study period in watersheds from the Qaidam Basin and headwater sources of the Yangtze River, the decreased LAI due to grassland degradation and the associated declines in ET and increases in soil moisture collectively led to significant increases in TWS in these watersheds (Figures 6b and A4c,d). On the contrary, watersheds in the southern and southeastern Qinghai–Tibet Plateau are dominated by alpine forest, meadow, and glaciers with declined precipitation and soil moisture and increased ET and glaciers retreat due to global warming (Figures 6a–c, A3 and A4d). The reduced precipitation and increased ET and glacier loss are the major contributors to significant declines in TWS in these alpine watersheds, with complex responses of alpine forests and meadows to climate warming. In addition, growing agricultural activities may also contribute to reductions in TWS in the alpine forest-dominated southern Qinghai–Tibetan Plateau, but their negative effects on TWS were offset by climate change impact in the grassland-dominated northern Qinghai–Tibetan Plateau [79,80] (Figures 4, 7 and A5b).

TWS generally remains nonstationary and shows an insignificant trend during the study period in mild-cold temperate zone watersheds (Tables 3 and 4), which is mainly caused by the differences in TWS trends and associated drivers across this climate zone (Figure 5). The downward tendency of TWS is mostly detected in watersheds located in the eastern mild temperate zone (e.g., the Inner Mongolia Plateau), which is mainly due to growing water use as a result of ambitious agriculture expansion (Figures 4 and 7) and accelerated grassland degradation (e.g., grazing activities) (Figure 6b) over the study period. Contrarily, due to the increased precipitation and evapotranspiration, and decreased temperature and population density, an upward tendency in TWS is found in watersheds in the cold temperate zone (e.g., Xiaoxing’anling mountains) where boreal coniferous and deciduous broadleaf forests are dominant, as well as seasonally frozen soils. Increased LAI and associated increments in ET are caused by newly regenerated or planted young forests, and these trees would consume more water than old-growth trees [81,82]. However, a significant water surplus occurs since the climate change effect (significant increments in precipitation and effective precipitation, and increased soil water resulting from accelerated and advanced melting of frozen soils) outweighs the above-ground ET losses due to forest growth (Figures 4, 7 and A3). Interestingly, TWS in watersheds in mild-cold climate zones is positively related to NDVI but negatively related to LAI and VFC. Although these vegetation indices are widely used for monitoring, analyzing, and mapping temporal and spatial variations in vegetation structure, and describing biophysical traits, the relationships between these indices are complex given their differences in definitions and data sources [52–54]. Firstly, NDVI and LAI may not always have positive correlations [83,84]. For example, Ma et al. [83] found

that the observation angles directly determine the accuracy of LAI and *NDVI* estimations, where *NDVI* decreases with increasing observation angles while there is a large value in LAI. Danson et al. [84] also found that there was no significant relation between LAI and *NDVI* when the value of LAI is larger than 6 based on remotely sensed data. Secondly, *NDVI* usually increases with rising *VFC* when *VFC* is low. However, their relationship can be negative when *VFC* is high given that the *NDVI* value may converge to 1 [85]. Therefore, *NDVI* may have a saturation problem and be insensitive to vegetation change especially in these cold temperate watersheds with dense coniferous forests [86]. This indicates the usage of *NDVI* for vegetation change in these watersheds should be cautious.

4.2. Limitations and Uncertainties

There are some uncertainties and limitations in our study associated with the selection of indices, the study period, and the research method. These 16 indices were selected according to existing studies. To describe watershed characteristics, we only involve vegetation indicators and soil moisture, while other soil metrics (e.g., soil porosity and texture) and topographic and landscape indices may also have impacts on TWS [87,88]. Moreover, permanent water storage (e.g., glaciers) is an important component of TWS. In the context of global warming, the glaciers would melt and affect local and downstream TWS [17]. However, there is a lack of detailed data describing glacier dynamics and other watershed characteristics (e.g., soil, topography, and landscape). Second, although this study fills the research gap that assesses TWS dynamics at large spatial scales in China, the study period of our study is relatively short. Admittedly, the longer the study period allows us to capture more robust trends and spatial patterns as well as their associated mechanisms. Future assessment of TWS dynamics with a longer study period should be performed if more data are available. In addition, uncertainties may arise from data products provided by different sources. For example, although the GLASS LAI products have been widely used, they have some limitations, such as the high dependence on the quality of surface reflectance [89]. The spatial resolution of GRACE data may also cause uncertainty in retrieving TWS. For the 214 watersheds, we only have 20 watersheds with a size of less than 10,000 km², and the effect of spatial resolution on retrieving TWS is limited. Assessing quantitative relationships between TWS dynamics and different drivers could largely improve our understanding of the relative contributions of drivers to TWS. However, the quantitative estimations are difficult to validate since there is a lack of field data and effective quantification methods. Thus, our study focuses on qualitative correlations between TWS dynamics and drivers. Future studies and field samplings are needed to validate the accuracy of data from different sources.

5. Conclusions

The dynamics of TWS and their driving factors at a relatively large scale are rarely evaluated in China. Our assessment demonstrated that China experienced water deficits over the period from 2004 to 2014. Climate variability, watershed characteristics, and anthropogenic activities can significantly affect TWS. We conclude that dominating factors of TWS dynamics across climate zones are different. Our study indicates that researchers need to identify the major contributing factors to TWS in their study areas and suggests that watershed management strategies should be designed for watersheds from different climate zones with a comprehensive understanding of their specific TWS dynamics and driving mechanisms.

Appendix B

According to Figure A3a, significant increments ($p < 0.05$) in precipitation (P) are mainly detected in tropical, central warm temperate (particularly the Loess Plateau), and eastern mild-cold temperate watersheds, while significant decrements ($p < 0.05$) are found in watersheds located in alpine and eastern warm temperate climate zones. Effective precipitation (PE) significantly increases in warm temperate watersheds, whereas it significantly decreases in alpine and southwestern subtropical watersheds (Figure A3b). For significant changes in evapotranspiration (ET), most watersheds have increasing trends, while significant decrements in ET are identified in watersheds from northern subtropical and eastern warm temperate zones (Figure A3c). Additionally, temperature (T_{ave}) shows significantly positive trends ($p < 0.05$) in watersheds in tropical, subtropical, alpine, warm, and western mild-cold temperate climate zones, while significantly negative variations ($p < 0.05$) occur in Northeast China experiencing the mild-cold temperate climate (Figure A3d).

Figure A4a suggests that LAI significantly increases ($p < 0.05$) in watersheds in tropical, subtropical, warm temperate, and mild-cold temperate climate zones. Significant increasing trends of NDVI are found in most study watersheds (Figure A4b). According to Figure A4c, significant increasing trends ($p < 0.05$) in VFC occur in alpine, subtropical, central warm temperate, and mild-cold temperate watersheds. For changes in SM (Figure A4d), significant upward trends ($p < 0.05$) are tested in tropical, southern subtropical, mild-cold temperate, and western warm temperate watersheds, while significant declines ($p < 0.05$) are observed in alpine and eastern warm temperate watersheds.

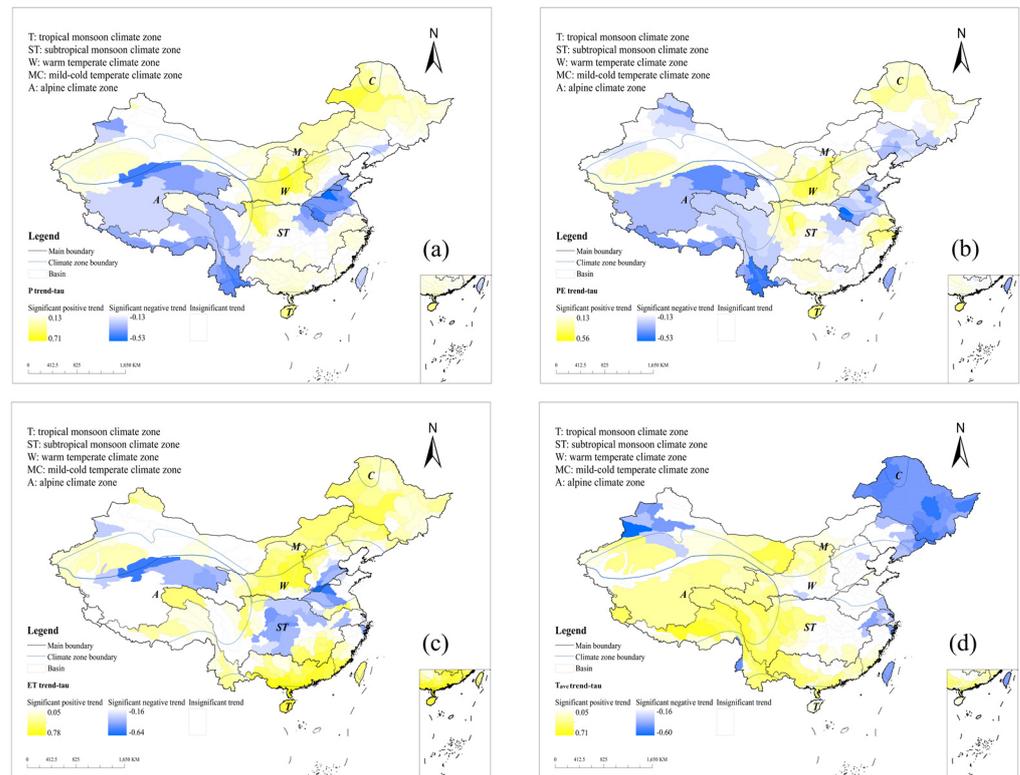

Figure A3. The spatial distributions of significant temporal trends ($p < 0.05$) of (a) P ; (b) PE ; (c) ET ; and (d) T_{ave} .

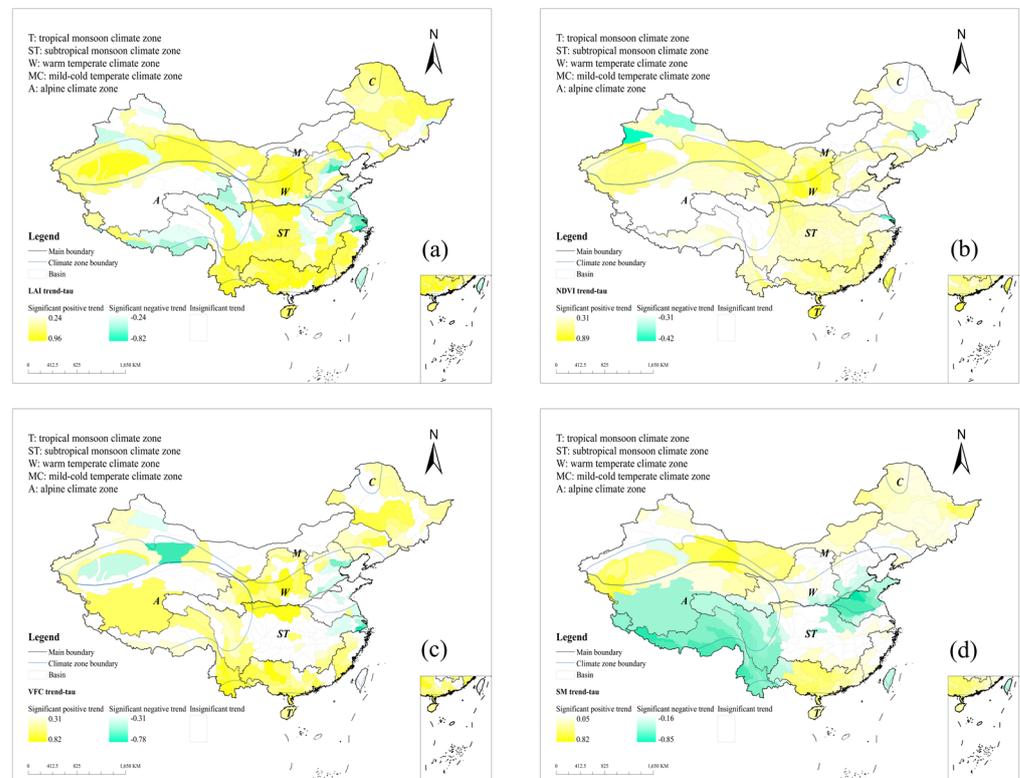

Figure A4. The spatial distributions of significant change trends ($p < 0.05$) of (a) LAI ; (b) $NDVI$; (c) VFC ; and (d) SM .

The trend analysis indicates that industry water consumption (IND) undergoes significant increments ($p < 0.05$) in watersheds in mild-cold temperate, western alpine, and subtropical climate zones (Figure A5a). A significant upward trend ($p < 0.05$) in agricultural water use (AGR) is explored in watersheds located in the east and west of mild-cold temperate, alpine, central subtropical monsoon, and western warm temperate climates (Figure A5b). Compared with other climate zones, the changes in domestic water consumption (DW) significantly decrease in the south of alpine watersheds (Figure A5c). In addition, total water use (WT) has significant increasing trends (Figure A5d). In Figure A5e, there are markedly positive trends in irrigation area (IRR) in China except for watersheds in the central warm temperate climate zones. Lastly, there are significant decreasing trends in population density (PD) in watersheds located in the north of mild-cold temperate and the central subtropical monsoon climate zones, while other regions have significantly increasing PD (Figure A5f).

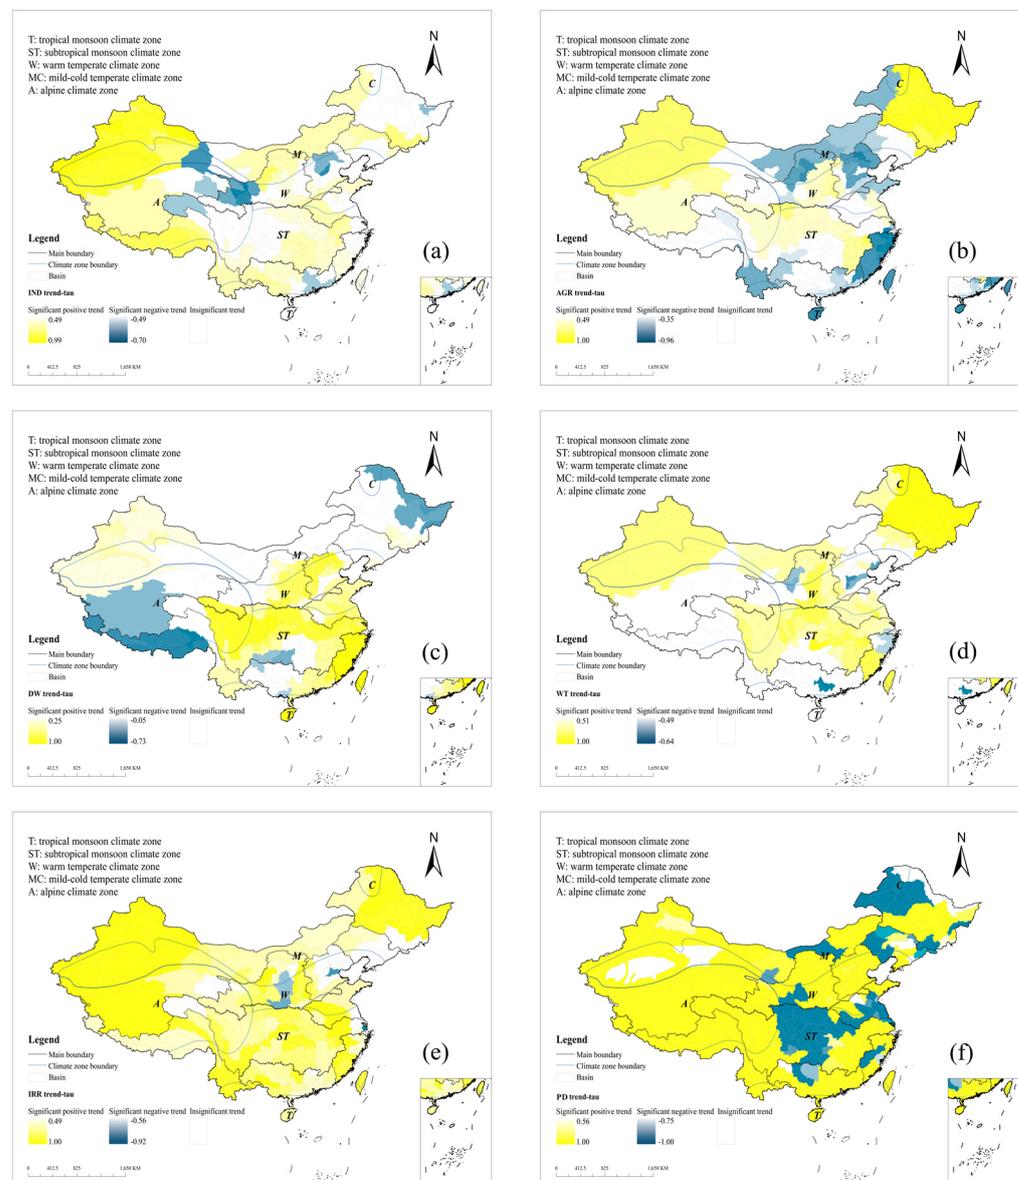

Figure A5. The spatial distributions of significant change trends ($p < 0.05$) of (a) IND; (b) AGR; (c) DW; (d) WT; (e) IRR; and (f) PD.

Note: T, ST, W, MC, and A denote tropical monsoon, subtropical monsoon, warm temperate, mild-cold temperate, and alpine climate zones, respectively. The positive values of MK tau denote increases in TWSAs, while negative values mean decreases. * Indicates significant at $\alpha = 0.05$.
