**Abstract:** Carbon and oxygen isotope ratios ( $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$ ) were measured in annual tree-ring cellulose samples dated from 1756 to 2015 CE. These samples were extracted from Chinese pine (*Pinus tabulaeformis* Carr.) trees located in a semi-arid region of north-central China. We found that tree-ring  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values both recorded similar climatic signals (e.g., temperature and moisture changes), but found that tree-ring  $\delta^{13}\text{C}$  exhibited a stronger relationship with mean temperature, precipitation, average relative humidity, self-calibrating Palmer drought severity index (scPDSI), and standard precipitation evaporation index (SPEI) than  $\delta^{18}\text{O}$  during the period 1951–2015 CE. The strongest correlation observed was between tree-ring  $\delta^{13}\text{C}$  and scPDSI (previous June to current May), which explains ~43% of the variance. The resulting 130-year reconstruction reveals severe drought events in the 1920s and a sustained drying trend since the 1980s. This hydroclimate record based on tree-ring  $\delta^{13}\text{C}$  data also reveals similar dry and wet events to other proxy data (i.e., tree-ring width and historical documentation) that have allowed reconstructions to be made across the northern fringe of the Asian summer monsoon region. Our results suggest that both large-scale modes of climate variability (e.g., El Niño-Southern Oscillation, Pacific Decadal Oscillation, and North Atlantic Oscillation) and external forcing (e.g., solar variability) may have modulated moisture variability in this region. Our results imply that the relationship between tree-ring  $\delta^{18}\text{O}$  and local climate is less well-characterized when compared to  $\delta^{13}\text{C}$  and may be affected more strongly by the influences of these different atmospheric circulation patterns. In this semi-arid region, tree-ring  $\delta^{13}\text{C}$  appears to represent a better tool with which to investigate historical moisture changes (scPDSI).

## 1. Introduction

Recent changes in the distribution of precipitation along the northern fringe of the Asian summer monsoon (ASM) region in north-central China are believed to have been influenced by the changing intensity of the Asian monsoon and westerly atmospheric circulation patterns in the semi-arid zone [1]. The Ha Si Mountain (HSM) nature reserve is located at the northern edge of the ASM and on the boundary of several semi-arid regions. The HSM is bordered to the north by the Tengger Desert, to the southeast by the Yellow River, and to the west by the north-eastern Tibetan Plateau. This unique geographical position makes the HSM one of China's most important water conservation regions. The western and southern part of the HSM is influenced by a westerly wind and the ASM system, respectively. Therefore, changes to hydroclimate have important effects on agriculture and the economy in this region. Severe drought events in the past millennium have occurred over different timescales and have had negative socio-economic impacts on

regions near the HSM [2,3]. Recent studies suggest that drought events will intensify and become more frequent with global warming, largely due to decreased precipitation and increased evaporation [4]. An improved understanding of long-term moisture variability and the complex moisture sources that influence this particular region is needed to manage resources more effectively and to further reduce uncertainties in climate models used to describe the effects of global warming.

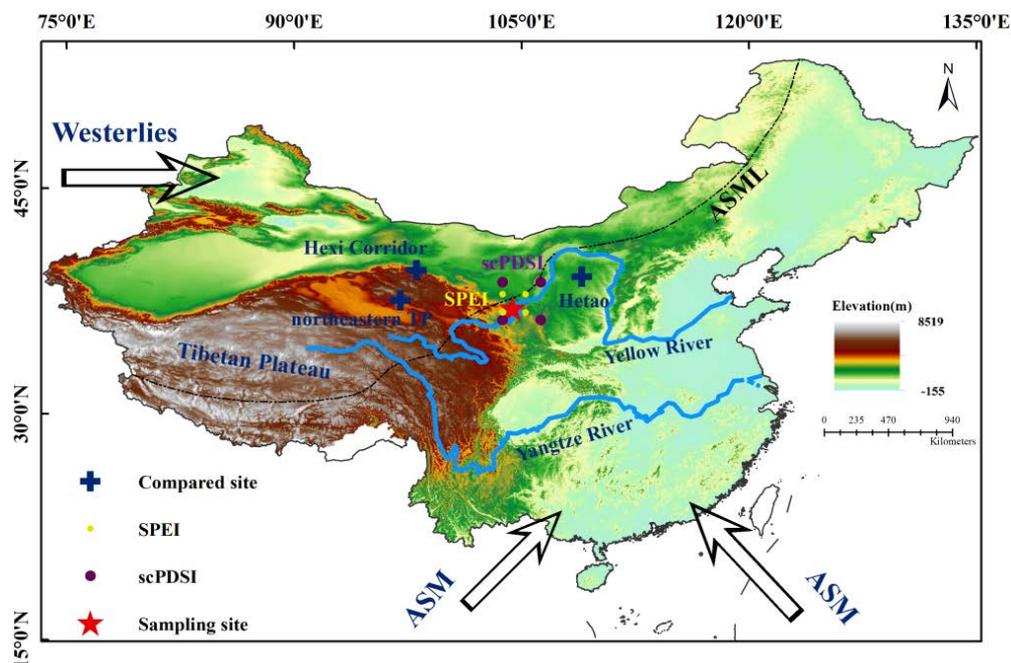

Over the past decades, substantial efforts have been made to reconstruct past climate changes across East Asia using tree rings [5–8]. Tree-ring stable isotopes data require fewer samples to be analyzed compared to the interpretation of ring widths in classical dendroclimatology [9]. Tree-ring stable isotopes can track temporal changes in how trees use carbon dioxide and water and record how these changes relate to environmental (climatic) controls. Tree-ring  $\delta^{18}\text{O}$  data reflect the isotopic composition of local moisture, rainfall, or atmospheric circulation patterns, which may be modified by environmental or physiological factors [10]. Tree-ring stable isotopes, therefore, have become an important proxy for reconstructing paleoclimate variations with the advantages of precise physiological mechanisms [11] and more reliable climate signals [12–16]. Previous tree-ring research in China has demonstrated that  $\delta^{18}\text{O}$  variability may be sensitive to changes in hydroclimate [17–22]. Stable carbon isotopes in tree rings should reflect environmental controls affecting carbon assimilation (i.e., related to solar insolation and temperature) and stomatal conductance (i.e., related to hydroclimate and moisture stress) [23,24]. Studies of tree-ring  $\delta^{13}\text{C}$  in China have shown instability in the climate signals preserved in trees from the Qinghai-Tibetan Plateau [25] and western China [26]. More research is required to better understand these indicators and to determine the dominant (local) climatic controls on tree-ring  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$ .

Previous studies have focused on the suitability of tree-ring widths as a record of the Palmer drought severity index [27] or tree-ring  $\delta^{18}\text{O}$  as a proxy for relative humidity [28] in HSM regions. However, it remains unclear to what extent tree-ring  $\delta^{13}\text{C}$  could be a potential proxy for climate variability in these regions. This study evaluates the relationships between tree-ring  $\delta^{13}\text{C}$  and regional climate changes and assesses the suitability of tree-ring  $\delta^{13}\text{C}$  as a proxy for changes in moisture in this region, which may, in turn, be useful for monitoring and predicting monsoon variability through time.

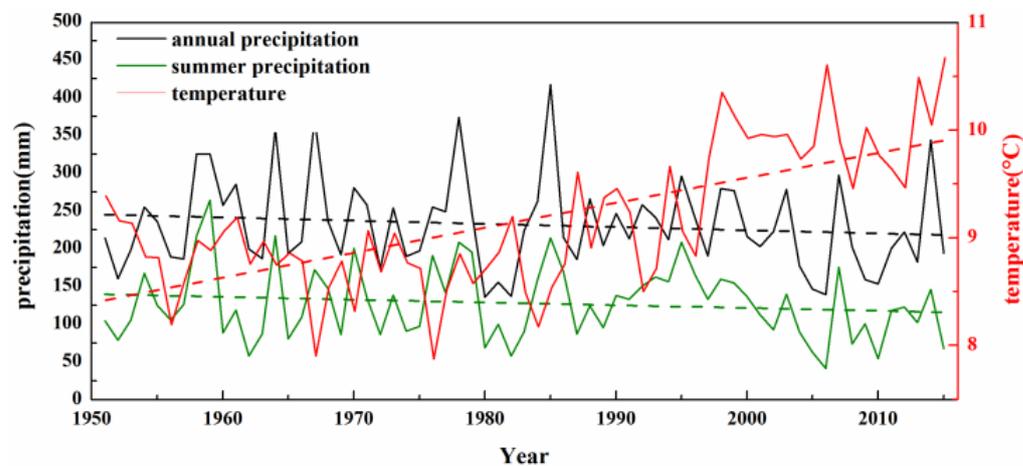

## 2. Materials and Methods

### 2.1. Sampling Site

Tree-ring samples were extracted from Chinese pine (*Pinus tabulaeformis* Carr.) trees situated in the HSM nature reserve (104.6° E, 37° N, 2400–3017 m above sea level) in the Jingyuan County, Gansu Province (Figure 1). The average annual precipitation at the Jingyuan meteorological station during the period 1951–2015 CE was 232 mm, with more than 55% of the annual precipitation concentrated in the summer months (i.e., from June to August). Mean annual precipitation trend (−0.42 mm/year) and summer rain trend (−0.39 mm/year) showed a similar decreasing trend from 1951 to 2015 CE (Figure 2). The average annual temperature in the study region was 9.14 °C, which increased by around 0.04 °C/year after 1977 (Figure 2). Relative humidity decreased by −0.037% each year over the entire period of meteorological observation.

**Figure 1.** Sampling site (red star) within the HSM. Blue cross symbols represent comparison sites in Hetao [29], the Hexi Corridor [8], and the north-eastern Tibetan Plateau (TP) [30]. ASML and ASM are the mean Asian summer monsoon limit and Asian summer monsoon, respectively.

**Figure 2.** Mean annual precipitation, summer precipitation, and average annual temperature for the Jingyuan meteorological station during the period 1951–2015 CE. The dashed line indicates linear trend.

## 2.2. Sample Processing and Chronological Assessment

Chinese pine is the dominant species in the study area but grows sparsely on the northern slope of the HSM. A tree-ring width chronology covering the period 1681 to 2010 CE was first developed in this region by [27]. Twenty-two new cores were collected in the same region in the year 2015 CE to update this tree-ring width chronology, with these samples also being subjected to stable isotope analysis. We extracted the samples with increment borers at the breast height, following the common dendrochronological standard [31,32].

Nine of the dated tree cores that exhibited the smallest number of narrow or locally absent rings were selected for stable isotope analysis. The whole annual ring (early- and late-wood) was cut into thin slivers using a scalpel under a binocular microscope before preparation of  $\alpha$ -cellulose [33,34]. Subsequently, 0.30–0.35 mg of dry  $\alpha$ -cellulose was

weighed into silver capsules for pyrolysis into CO, and mass spectrometry was performed using a Flash HT elemental analyzer interfaced with a Delta V IRMS. Both carbon and oxygen isotope ratios were measured simultaneously [35,36]. The analytical precision of the tree-ring and cellulose standards was typically better than 0.1‰ and 0.3‰ for  $\delta^{13}\text{C}_{\text{VPDB}}$  and  $\delta^{18}\text{O}_{\text{VSMOW}}$ , respectively.

The  $\delta^{13}\text{C}$  “Suess” correction method [23] was used to adjust the tree-ring  $\delta^{13}\text{C}$  series for post-industrial changes in the  $\delta^{13}\text{C}$  value of atmospheric carbon dioxide. Each corrected tree-ring  $\delta^{13}\text{C}$  series was then adjusted for changes in the physiological response of trees to increases in CO<sub>2</sub> concentration [37]. No corrections were made to the oxygen isotope series.

The 9 samples that underwent stable isotope analyses were 90–260 years old, and 7 of the trees had pith preserved. In order to avoid possible “juvenile” trends, we discarded the first 30 years of isotope data when conducting further analyses [38].

### 2.3. Climatic Data and Statistical Analyses

The expressed population signal (EPS) and mean inter-series correlation (Rbar) [39] were calculated to determine the strength of the common signal between tree-ring  $\delta^{13}\text{C}$  and the  $\delta^{18}\text{O}$  series. Monthly temperature, precipitation, and relative humidity data acquired by the Jingyuan meteorological station from 1951 to 2015 CE were calculated and correlated with both stable isotope series. Self-calibrating Palmer drought severity index (scPDSI) [40] data and global standard precipitation evaporation index (SPEI; with a 24-month timescale) data were obtained from the climatic research unit (CRU) from 1951 to 2015 CE. The obtained scPDSI and SPEI data completely cover the HSM area (Figure 1). The responses and correlation analysis between climatic data and each stable isotope series were performed using the DendroClim2002 software [41].

A linear regression model was employed to reconstruct climate from tree-ring  $\delta^{13}\text{C}$  data. To verify the reconstruction, we calculated the correlation coefficient ( $R$ ), the variance determined by the regression model ( $R^2$ ), the reduction of error statistic (RE), the coefficient of efficiency (CE), and performed leave-one-out verification analysis. We also calculated the  $\pm 1$  root mean square error (RMSE) in the reconstruction analysis.

The spatial relationship of correlations between reconstruction series and climatic data was explored using the KNMI Climate Explorer software (Royal Netherlands Meteorological Institute; <https://climexp.knmi.nl/>, accessed on 5 November 2021). We applied the multi-taper method (MTM) [42] of spectral analysis to investigate the periodicity of the reconstruction.

## 3. Results and Discussion

### 3.1. Climate and Tree-Ring $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ Chronology

Table 1 shows the average correlation among each  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  series. The correlation among each  $\delta^{13}\text{C}$  series was stronger than that of each  $\delta^{18}\text{O}$  series. Table 2 shows the statistical properties of the  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  series. Compared with the corresponding  $\delta^{18}\text{O}$  series, the EPS and Rbar for the  $\delta^{13}\text{C}$  series were also stronger (Table 2). The adjusted  $\delta^{13}\text{C}$  series and the sample depth of  $\delta^{13}\text{C}$  chronology are present in Figure 3a. Based on the threshold of EPS is exceeding 0.85 for the robustness of a chronology [39], we found that the most confident period of  $\delta^{13}\text{C}$  chronology was from 1884 to 2015 CE.

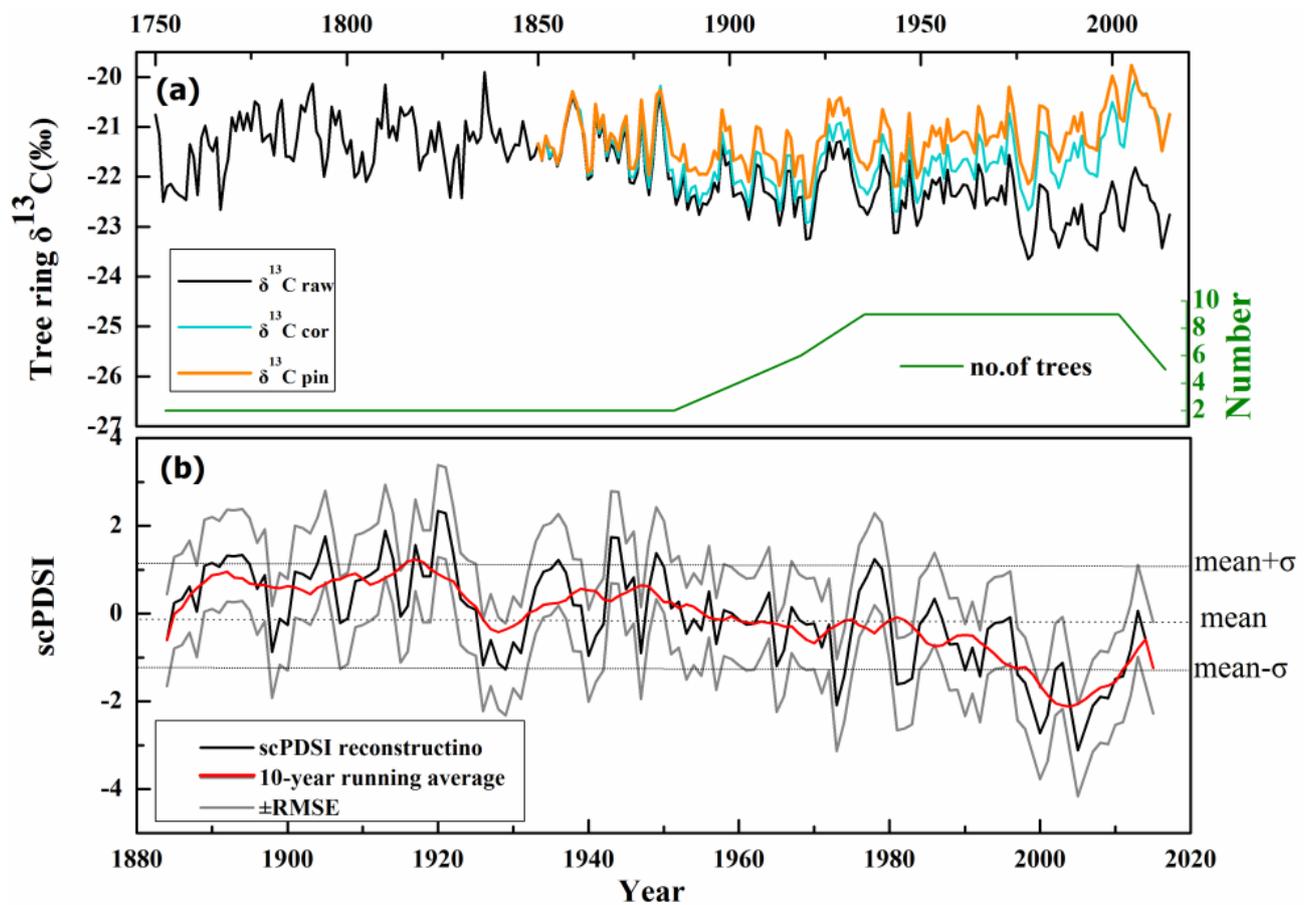

Correlation analyses were applied between our tree-ring isotope chronologies and monthly meteorological observation data collected from previous May to October in the following year for the period 1951–2015 CE. These observed meteorological data included average temperature, total precipitation, and average relative humidity data. Our results suggest significant positive correlations between tree-ring  $\delta^{13}\text{C}$  chronology and the mean temperature, but mostly negative correlations between tree-ring  $\delta^{13}\text{C}$  chronology and total precipitation and average relative humidity (Figure 4a). Compared to correlations between meteorological records and tree-ring  $\delta^{13}\text{C}$  chronology, weaker correlations occurred between tree-ring  $\delta^{18}\text{O}$  chronology and monthly mean temperature, total precipitation, and average relative humidity during the period with shared instrumental data (Figure 4a)

**Table 1.** The average correlations among each tree-ring  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  series.

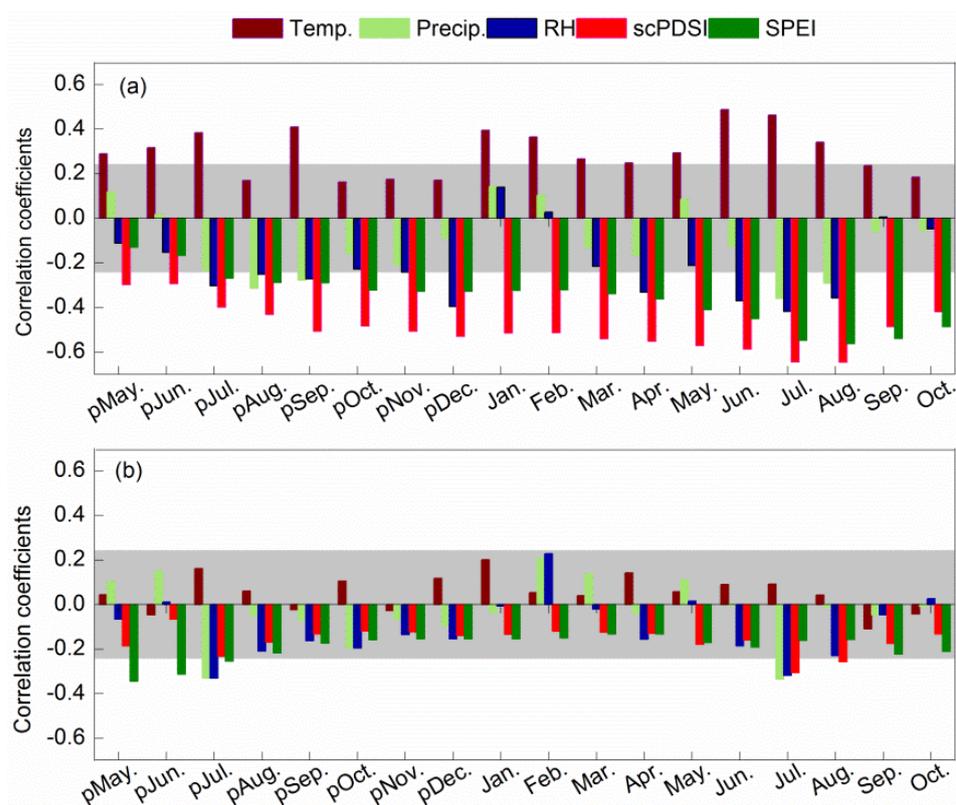

Samples	Tree-Ring $\delta^{13}\text{C}$								Tree-Ring $\delta^{18}\text{O}$

3			0.56	0.34	0.55	0.45	0.28	0.49			0.26	0.49	0.13	-0.07	0.23	0.25
4				0.66	0.75	0.48	0.52	0.34				0.56	0.47	0.47	0.36	0.27
5					0.55	0.50	0.43	0.31					0.26	0.25	0.51	0.35
6						0.63	0.59	0.49						0.50	0.20	0.27
7							0.29	0.66							0.13	0.03
8								0.26								0.36

**Table 2.** Characteristics of measured tree-ring  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  series.

	Tree-Ring $\delta^{13}\text{C}$	Tree-Ring $\delta^{18}\text{O}$
Time span (CE)	1750–2015	1750–2015
Mean (‰)	-21.87	32.61
Minimum (‰)	-23.65	29.18
Maximum (‰)	-19.90	36.63
Mean EPS	0.89	0.76
Mean Rbar	0.48	0.27

**Figure 3.** (a) shows tree-ring  $\delta^{13}\text{C}$  raw series derived from raw data, corrected tree-ring  $\delta^{13}\text{C}$  cor based on the method of [23], and tree-ring  $\delta^{13}\text{C}$  pin based on the method of [37]. (b) shows reconstructed annual scPDSI values for June (previous year) to May (current year) for the period from 1884 to 2015 CE. RMSE is the root mean square error.

**Figure 4.** Correlation coefficients for tree-ring  $\delta^{13}\text{C}$  (a) and  $\delta^{18}\text{O}$  (b) series with temperature, precipitation, relative humidity, scPDSI, and SPEI from June each year to October of the following year during the period from 1951 to 2015. Grey shaded bands indicate the 95% confidence level.

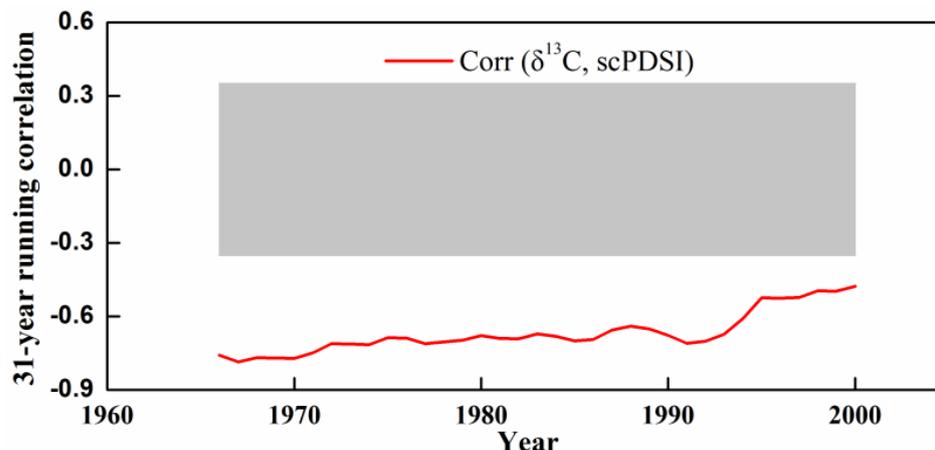

The observed correlations strengthen when evaluated over a three-month-long period of meteorological data are combined together. The strongest significant correlation at the 0.05 level was found between tree-ring  $\delta^{13}\text{C}$  chronology and mean June, July, and August (JJA) relative humidity ( $r = -0.59$ ). A second significant positive correlation was found between tree-ring  $\delta^{13}\text{C}$  chronology and temperature during JJA ( $r = 0.55$ ). Other significant correlations were found between tree-ring  $\delta^{13}\text{C}$  chronology and total precipitation for June and July (JJ) of each year ( $r = -0.48$ ). By contrast, tree-ring  $\delta^{18}\text{O}$  chronology had a less significant correlation with JJA average relative humidity ( $r = -0.3$ ). A significant negative correlation was found between tree-ring  $\delta^{18}\text{O}$  chronology and JJ total precipitation ( $r = -0.3$ ). Furthermore, no significant correlation was noted between tree-ring  $\delta^{18}\text{O}$  chronology and JJA mean temperature.

The results of correlation analyses suggest that humidity exerts a strong control on tree growth in this semi-arid region. Further comparison of monthly mean scPDSI and SPEI data from May in the previous year to the following October during 1951–2015 with tree-ring  $\delta^{13}\text{C}$  chronology suggests a stronger correlation than with tree-ring  $\delta^{18}\text{O}$  chronology, except for May to June data for mean SPEI (Figure 4b).

The strongest correlation between tree-ring  $\delta^{13}\text{C}$  chronology and seasonal combinations of mean scPDSI data was obtained from June to August ( $r = -0.662$ ). The correlation coefficients between the tree-ring  $\delta^{13}\text{C}$  chronology and the spring (March to May), autumn (September to November), and winter (December to February) seasons' mean scPDSI values were  $-0.581$ ,  $-0.450$ , and  $-0.519$ , respectively. The strongest correlation coefficients were observed for the combination of annual mean scPDSI from June in the previous year to May in the current year with tree-ring  $\delta^{13}\text{C}$  chronology ( $r = -0.656$ ,  $p < 0.05$ ).

We also calculated the correlation for first-difference data between annual mean scPDSI and tree-ring  $\delta^{13}\text{C}$  chronology ( $r = -0.48$ ,  $p < 0.05$ ) to explore climatic trends without the influence of long-term trend effects. We calculated the 31-year running correlations between

our tree-ring  $\delta^{13}\text{C}$  chronology and the scPDSI (Figure 5). The results show the correlations between tree-ring  $\delta^{13}\text{C}$  chronology and scPDSI generally exceeded  $-0.30$  and are significant at the 95% level over the instrumental periods (Figure 5). There were no climatic trends that influenced the long-term trend.

**Figure 5.** The 31-year running correlations between tree-ring  $\delta^{13}\text{C}$  chronology and scPDSI with significant ones at 95% confidence level expressing as falling outside of grey shading.

### 3.2. Reconstruction of scPDSI Using Tree-Ring $\delta^{13}\text{C}$

Based on correlation analysis performed between stable isotopes chronologies and the climatic data, tree-ring  $\delta^{13}\text{C}$  chronology was used to develop reconstructions of annual mean scPDSI from previous June to current May. A linear regression model explains 42.6% of scPDSI variance in the period 1951–2015. The reduction of error (RE) and coefficient of efficiency (CE) were both positive, and CE was smaller than RE (Table 3), which illustrates that the linear regression model is accurate [43]. This model was used to reconstruct the scPDSI history in this region for the period 1884 to 2015 CE (Figure 3b).

**Table 3.** Regression model statistics for different calibration and verification periods.

	Calibration (1951–1980)	Verification (1981–2015)	Calibration (1984–2015)	Verification (1951–1983)	Full Calibration (1951–2015)
$R$	0.69	0.41	0.74	0.41	0.66
$R^2$	0.48	0.17	0.55	0.17	42.6%
$R^2_{adj}$	0.46	0.14	0.54	0.14	-
RE	0.56	-	0.49	-	0.40 <sup>L</sup>
CE	-	0.53	-	0.47	-

$R$ —correlation coefficient;  $R^2$ —variance explained by the regression model;  $R^2_{adj}$ —adjusted explained variance of the regression model; RE—reduction of error statistic; CE—coefficient of efficiency; and L—leave-one-out verification; <sup>L</sup>—the value is calculated from the leave-one-out method.

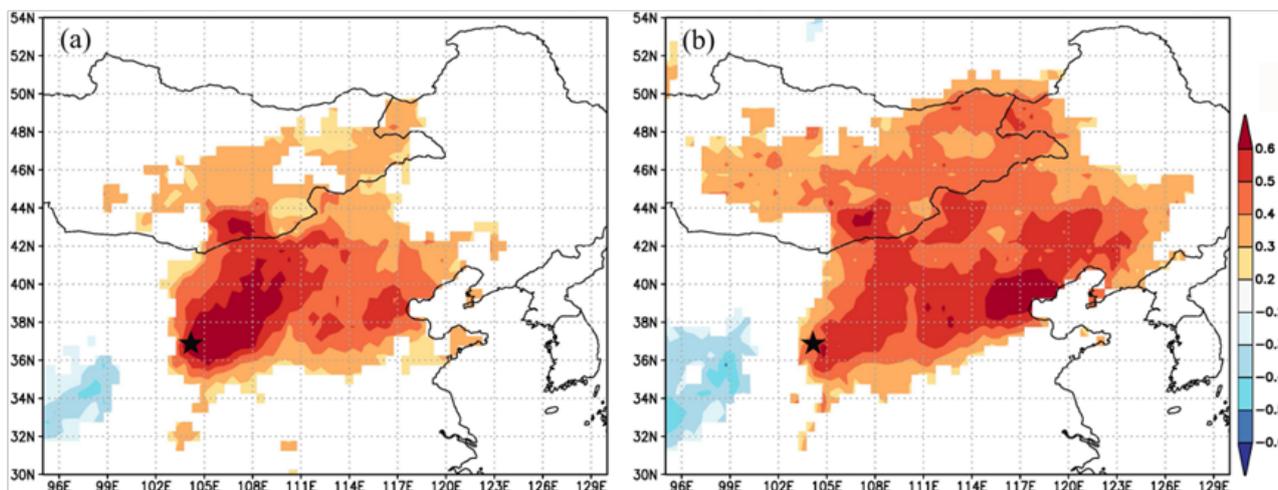

The mean value of our reconstructed scPDSI was  $-0.08$ , which is within the range of the defined near normal status ( $\pm 0.5$ ) [44]. To identify the presence of wet and dry conditions in our reconstruction, positive and negative values indicate wet and dry periods of the same category [44], respectively. The standard deviation ( $\sigma$ ) value is 1.1 for the whole chronology time span. We compared the severely wet and dry periods with nearby regions of drought reconstructions based on tree-ring and to avoid overestimation of the frequency of wet and drought conditions, scPDSI values that were more than one standard deviation ( $\sigma$ ) above or below the average value [28,45] were defined as slightly wet or dry years, respectively.

On an annual timescale, the years 1889–1895, 1904–1905, 1912–1914, 1917, 1920–1922, 1936, 1943–1944, 1949–1950, and 1978–1979 experienced slightly wet conditions (Figure 3b). The years 1926, 1928–1929, 1965, 1973–1974, 1981–1983, 1990, 1992, 1997–2002, 2004–2011,

and 2015 experienced slightly dry conditions (Figure 3b). On the decadal timescale, drought periods were identified in the 1920s and after 1980 (Figure 3b). The reconstruction of 10-year running mean values showed that the climate from 1884 to 1920 CE was notably wet, although there was an extremely dry event in the 1920s. After that event, a period with substantial rainfall lasted for around 30 years (from 1930 to 1960 CE), and then for a 10-year period in the 1970s. During those decadal periods, moisture characteristics fluctuated slightly, and short drought events were noted; however, a period of clear and prolonged drought occurred from 1980 to the present day (Figure 3b).

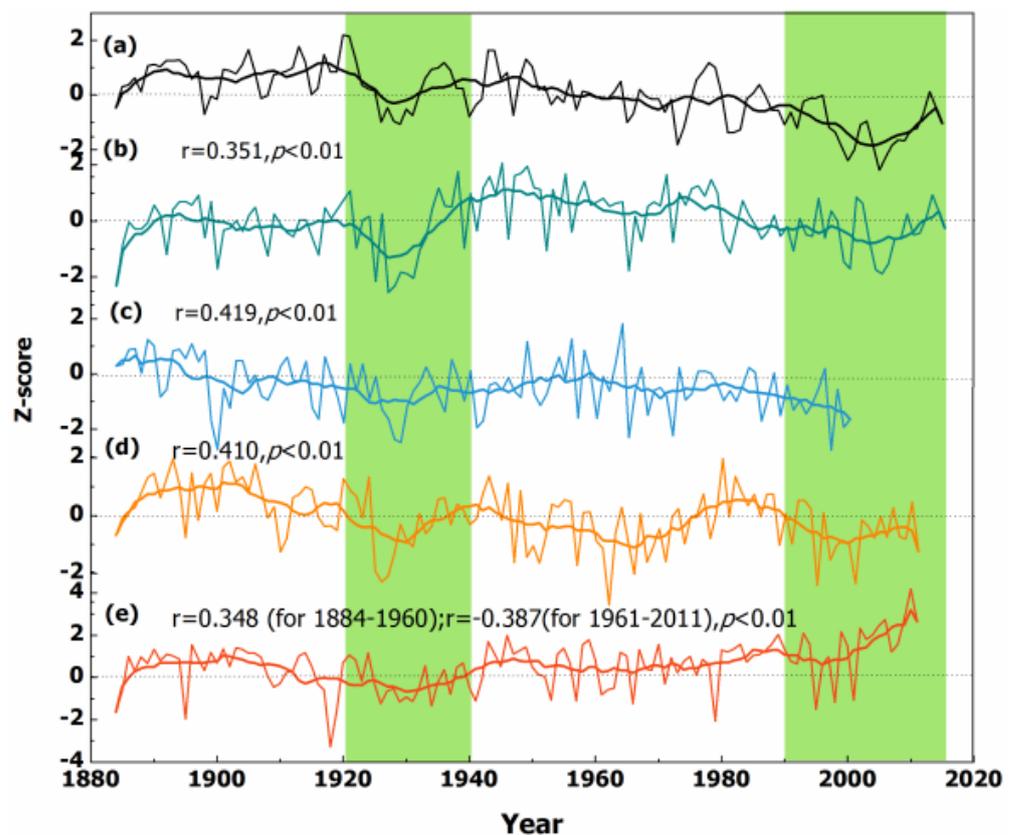

### 3.3. The Spatial Representation of Moisture Changes

The reconstructed scPDSI covers a wide spatial area during the period 1951 to 2015 (Figure 6). The strongest spatial correlation indices between our reconstruction and CRU scPDSI values are over 0.6 ( $p < 0.05$ ) and are located across the north-eastern fringe of the ASM in China. This strong correlation indicates that tree-ring  $\delta^{13}\text{C}$  can reliably record moisture variability in the northern fringe of the ASM region.

**Figure 6.** Spatial correlation results between reconstructed (a) and instrumental (b) scPDSI values with UCAR scPDSI collected from the period 1951 to 2015. The black star represents sampling site. Significant correlations at the 90% level are marked.

We compared our scPDSI reconstruction against the PDSI reconstruction generated by tree-ring width data in the HSM [27], an annual precipitation reconstruction [29] for Hetao based on historical documents, and early summer moisture reconstructions [8] in the Hexi Corridor (Figure 7a–d). The comparisons indicate that reconstructions share similar trends over the last 130 years and consistently capture drought signals in the 1920s and after the year 1990 to present at both annual and inter-annual timescales (Figure 7a–d). By contrast, precipitation reconstructions based on tree-ring widths in the north-eastern Tibetan Plateau (i.e., northwest of the HSM; Figure 1) clearly show climatic conditions from 1940 to the present day that are dominated by rainfall [30] (Figure 7e).

**Figure 7.** Tree-ring  $\delta^{13}\text{C}$  reconstruction in our study (a) compared with (b) PDSI reconstructions based on tree-ring width data from the HSM [27], (c) an annual precipitation reconstruction for Hetao [29], (d) an early summer moisture reconstruction in the Hexi Corridor [8], and (e) a precipitation reconstruction for the north-eastern Tibetan Plateau [30]. Common drought periods are indicated by green shaded bars. The  $r$  is the correlation coefficient between our reconstructions and other reconstructions in the common measurement periods ( $p < 0.01$ ). All of the series were normalized and smoothed with a 10-year moving average.

Discrepancies in moisture variation trends for HSM and the north-eastern Tibetan Plateau for the 56-year period from 1960 to 2015 CE may have been caused by increases in temperature. Analyses performed by [8,30] indicate that increased rainfall during the 20th century is consistent with higher temperatures in the north-eastern Tibetan Plateau; however, changes in moisture levels in the Hexi Corridor, where the drying trend is similar to that for the HSM, are predominantly limited by both temperature and precipitation [8]. The Hexi Corridor has become more arid, with global warming during the 20th century has caused increased evapotranspiration [8]. This difference suggests that temperature was highly influential on hydroclimatic conditions in the 20th century.

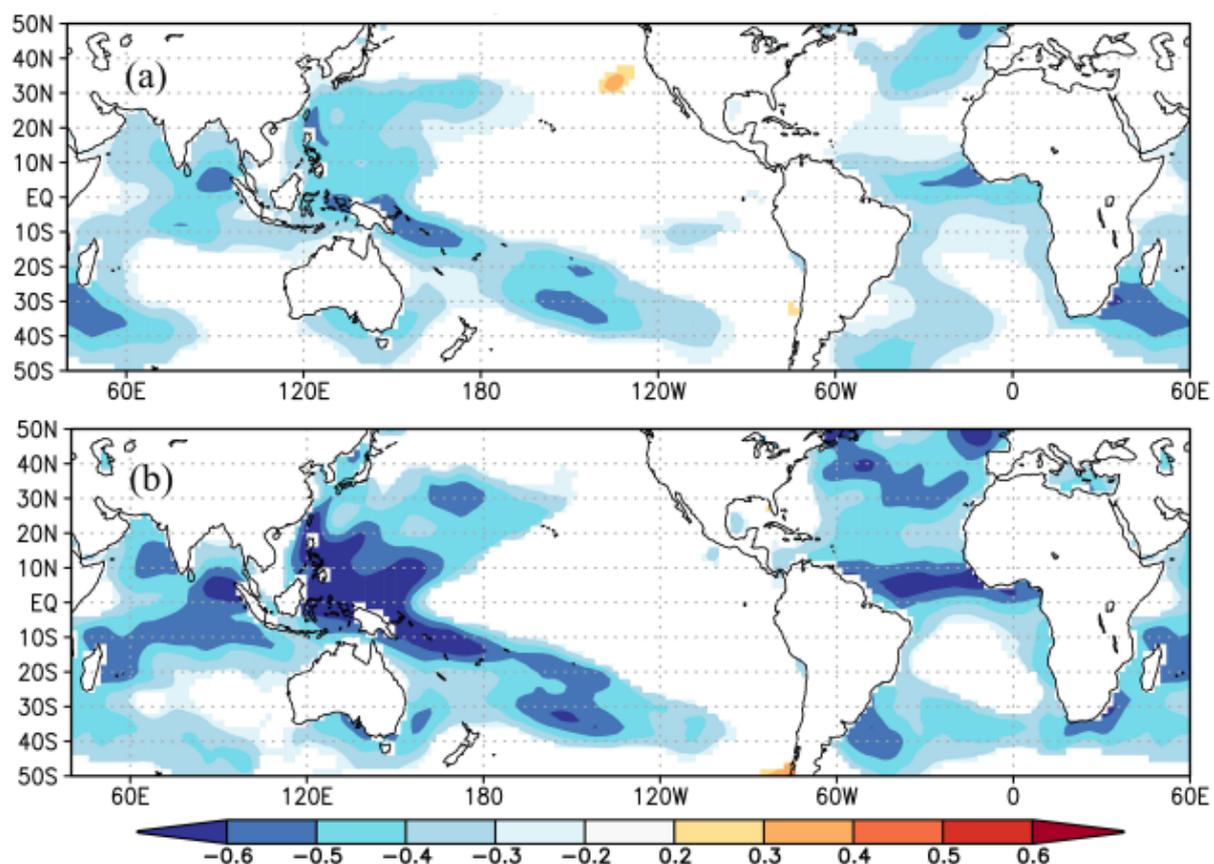

### 3.4. Forcing Factors of Hydroclimate Variability

The Hexi Corridor is located in the northwest corner of the ASM region, while the HSM and Hetao areas are located in the north-eastern fringes of the ASM region. Despite being situated far apart, the proxy records in each reveal that there were periods of drought and periods of wetness common to each, which may have been caused by similar broad-scale driving forces.

A MTM-method spectrum analysis was applied to extract the periodicities of our scPDSI reconstruction over the period 1884–2015 CE. The results show a 2- to 4-year inter-annual cycle and 11- year, 22- to 24-year decadal cycles at the 90% confidence level. The inter-annual spectral properties are possibly related to variation in the El Niño-Southern Oscillation (ENSO) intensity [46,47], and inter-decadal spectral properties may be associated

with high-frequency solar activity [48], Pacific Decadal Oscillation (PDO) cycles [49], and North Atlantic Oscillation (NAO) periodicity [50,51].

Figure 8 shows a significant negative ( $p < 0.01$ ) spatial correlation between our scPDSI reconstruction and sea surface temperature (SST) in the Indian Ocean, South China Sea, Pacific Ocean, and Atlantic Ocean during 1951–2015. These correlations indicated that moisture conditions in our study region were directly associated with large-scale ocean–land circulation systems. We found significant correlation coefficients between the South Asian Summer Monsoon index [52], East Asian Summer Monsoon index (EASM) [53], PDO index [54], and instrumental summer NAO (<https://climexp.knmi.nl/>; accessed on 5 November 2021) with our reconstruction of 0.23 ( $p < 0.05$ ,  $n = 117$  for 1884–2000 CE), 0.22 ( $p < 0.05$ ,  $n = 117$  for 1884–2000 CE),  $-0.21$  ( $p < 0.05$ ,  $n = 132$  for 1884–2015 CE), and 0.25 ( $p < 0.01$ ,  $n = 129$  for 1884–2012 CE), respectively. Further work is required to explore the nature and stability of these teleconnections.

**Figure 8.** Spatial correlation coefficient of the reconstructed scPDSI (a) and a 10-year running average scPDSI value (b) with the SST over the common measurement period from 1951 to 2014. Significant correlations at the 90% level have been marked.

Previous studies based on stalagmite data [55] have suggested that water vapor and precipitation in China are mainly sourced from southwest air currents that originate from the Indian Ocean. Atmospheric activity over the Pacific Ocean in subtropical highs can affect the transmission of water vapor in the southwest airflow, which in turn affects the amount of water vapor transported by the southeast monsoon from the Pacific Ocean to mainland China. The western Pacific subtropical high therefore plays an important role in modulating the water vapor distribution in the East Asian monsoon region [55]. When the Indian Ocean and the Middle East Pacific SST were low, the West Pacific subtropical high region receded to the north and weakened. As the monsoon in China is mainly controlled by the intertropical convergence zone (ITCZ), more water vapor provided from

the Southern Indian Ocean [55] leads to increased precipitation in the monsoonal region of North China (i.e., the HSM). When the Middle East Pacific SST is high, the PDO is in a warm phase, meaning that a weaker EASM occurs over northern China and less water vapor transportation northwards, which reduces the amount of rainfall that falls in North China [56]. The dry periods in the HSM in the 1920s are consistent with PDO warm phases in the 1920s–1940s and very strong El Niño events in 1925 and 1926 [57].

The NAO is another well-known global atmospheric pressure field that records the intensity of westerly circulation [58]. Recent studies have shown that the summer NAO may affect the EASM [59]. It is worth noting that the EASM has been weakening since 1960 [53], concurrent with the phase reversal of the summer NAO in the 1960s [60]. In addition, a transition from a cool PDO phase to a warm PDO phase occurred in the mid-1970s [56], which has been associated with a period of drought that initiated in 1960 CE (Figure 3b). No notably wet conditions were predicted after 1980 CE (Figure 3b) in our reconstruction.

Based on the above discussion, the moisture conditions in our study region are clearly influenced by several different circulation modes. Moreover, the HSM is located at the margins of monsoonal regions, such that moisture fluxes may come from westerly and northerly winds, monsoons, and more local circulation patterns. Such complex water vapor sources may lead to tree-ring  $\delta^{18}\text{O}$  values recording hydroclimate signals that are more difficult to characterize using station data than tree-ring  $\delta^{13}\text{C}$  values. The fractionation of tree-ring  $\delta^{13}\text{C}$  is mainly controlled by stomatal conductance and the rate of photosynthesis [23,24]; however, the influence of large-scale atmospheric circulation on tree-ring  $\delta^{13}\text{C}$  can be neglected in the semi-arid HSM region. Therefore, tree-ring  $\delta^{13}\text{C}$  is an effective proxy in monsoon-margin regions to decipher the local hydroclimatic signal. Whereas precipitation in the north-eastern Tibetan Plateau [30] primarily comes from the recycling of continental moisture through convective processes during the summer, tree-ring  $\delta^{18}\text{O}$  data in this arid region can still preserve strong climate signals [3]. Further analyses are nevertheless needed to further verify these findings and better characterize the climate sensitivity of tree-ring  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values from different climates and geographic regions.

#### 4. Conclusions

Tree-ring  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  data from nine Chinese pines (*Pinus tabulaeformis* Carr.) growing on the northern fringe of the ASM region were measured to test their effectiveness as potential climate proxies. Tree-ring  $\delta^{13}\text{C}$  was found to be strongly and negatively correlated with scPDSI and was used to develop a scPDSI reconstruction from 1884 to 2015 CE that explained 42.6% of the variability in scPDSI during the instrumental period. Tree-ring  $\delta^{18}\text{O}$  data showed significant correlations with precipitation amount and relative humidity. The scPDSI reconstruction showed that there were 26 years of drought and 23 years of heavy rainfall when data were analyzed at an annual timescale, and periods of prolonged drought were identified in the 1920s and since 1980 to the present day when the data were analyzed at a decadal timescale. Analysis of trends in scPDSI reconstructions based upon tree-ring  $\delta^{13}\text{C}$  data and other hydroclimate reconstructions of nearby regions showed similar dry-wet fluctuations, especially during periods of extreme drought. Indeed, MTM analysis identified inter-annual cycles with 2- to 4-year periods and 11-year, 22- to 24-year decadal cycles in our reconstruction, which may indicate linkages with ENSO, solar activity, PDO, and NAO, which have been shown in other studies to directly impact hydroclimatic variability in our study region and modulate climate variations in north-central China. The complexity of water sources in HSM is a possible reason why tree-ring  $\delta^{18}\text{O}$  records exhibit weaker climate signals against station data than tree-ring  $\delta^{13}\text{C}$ . Whilst further work is required to develop the interpretation of these isotope proxies, our study has demonstrated that tree-ring  $\delta^{13}\text{C}$  data in this region record a stable hydroclimate signal that is suitable for development as a palaeoclimate record and potential source of information with which to inform water-resource management.
