

Supplementary Data

Concept of Double logistic curve:

In this study, we used the double logistic function because double logistic based curve fitting has been specifically designed for monitoring vegetation activity at high latitudes, where snow cover is present during the winter season. It was proposed by Beck et al., [1] and tested on the time series MODIS NDVI data extracted for Northern European boreal region. It estimates the NDVI and EVI of the vegetation during winter and applies a double logistic function, which is uniquely defined by six parameters that describe the yearly NDVI time series. It is already proven in previous studies that double logistic function does not overestimate the duration of the growing season and it handles outliers effectively and estimates parameters that are related to phenological events, such as the timing of spring and autumn. This makes the method most suitable for both estimating biophysical parameters and monitoring vegetation phenology at higher latitudes such as Boreal regions [1–3].

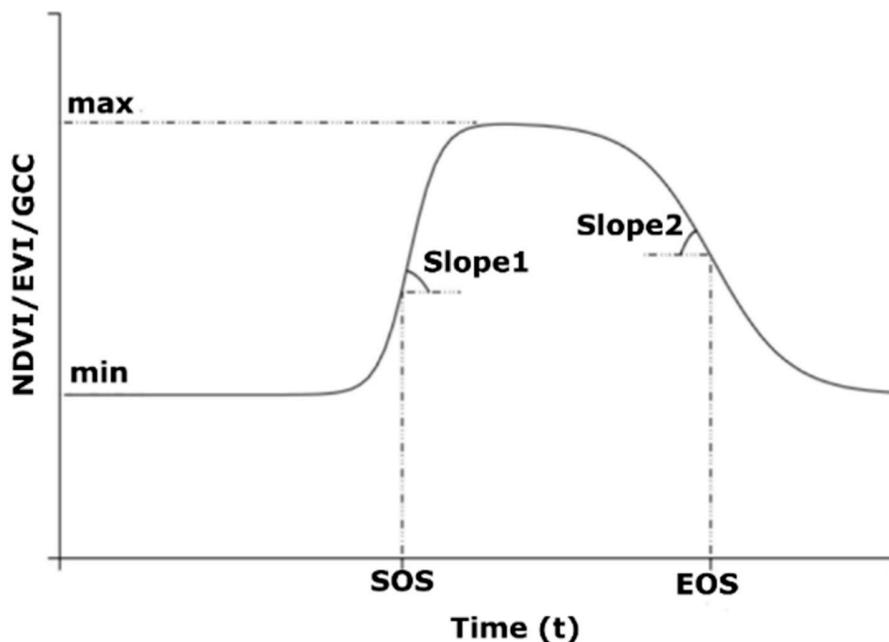

Figure S1: Example of the double logistic function (Eq. 4 in the manuscript) used to model the yearly NDVI/EVI/GCC time series. It is defined by six parameters: min and max are the minimum and maximum values measured in winter and summer, respectively, SOS and EOS are the inflection points when the curve rises and falls, and slope1 and slope2 are the rates of increase and decrease of the curve at the inflection points.

Figure S2. Example raster image of MODIS 250 spatial resolution data (base layer) and selected layover polygons (represented with black colour) from Quebec Forest inventory around PhenoCam tower site (represented with green star).

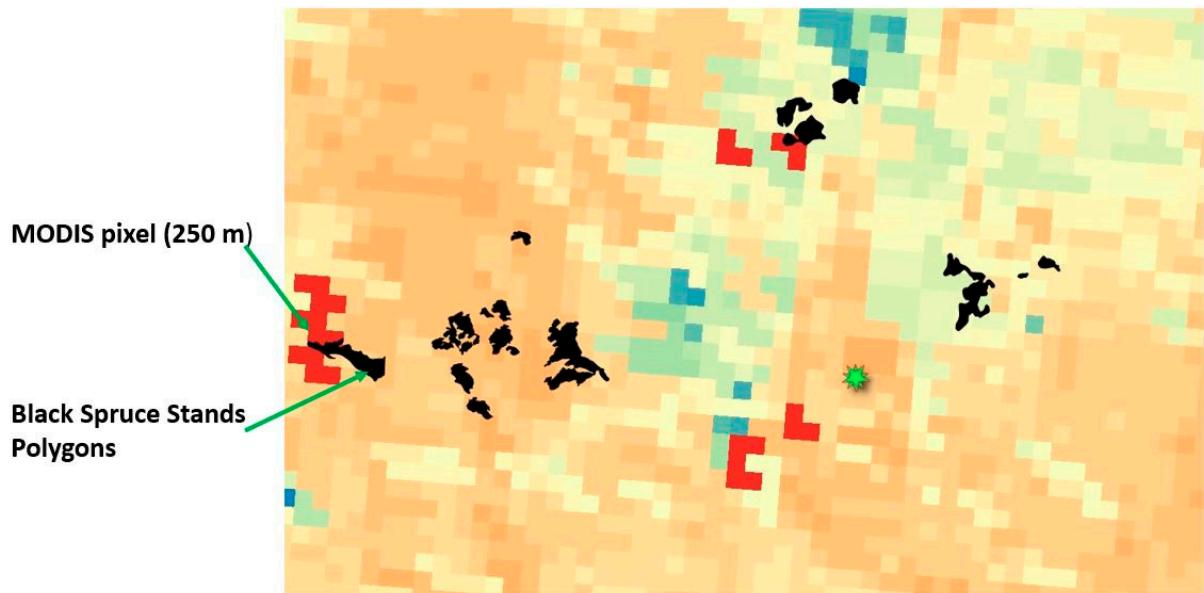

Figure S3: Statistical relationship between GCC and vegetation indices (NDVI and EVI).

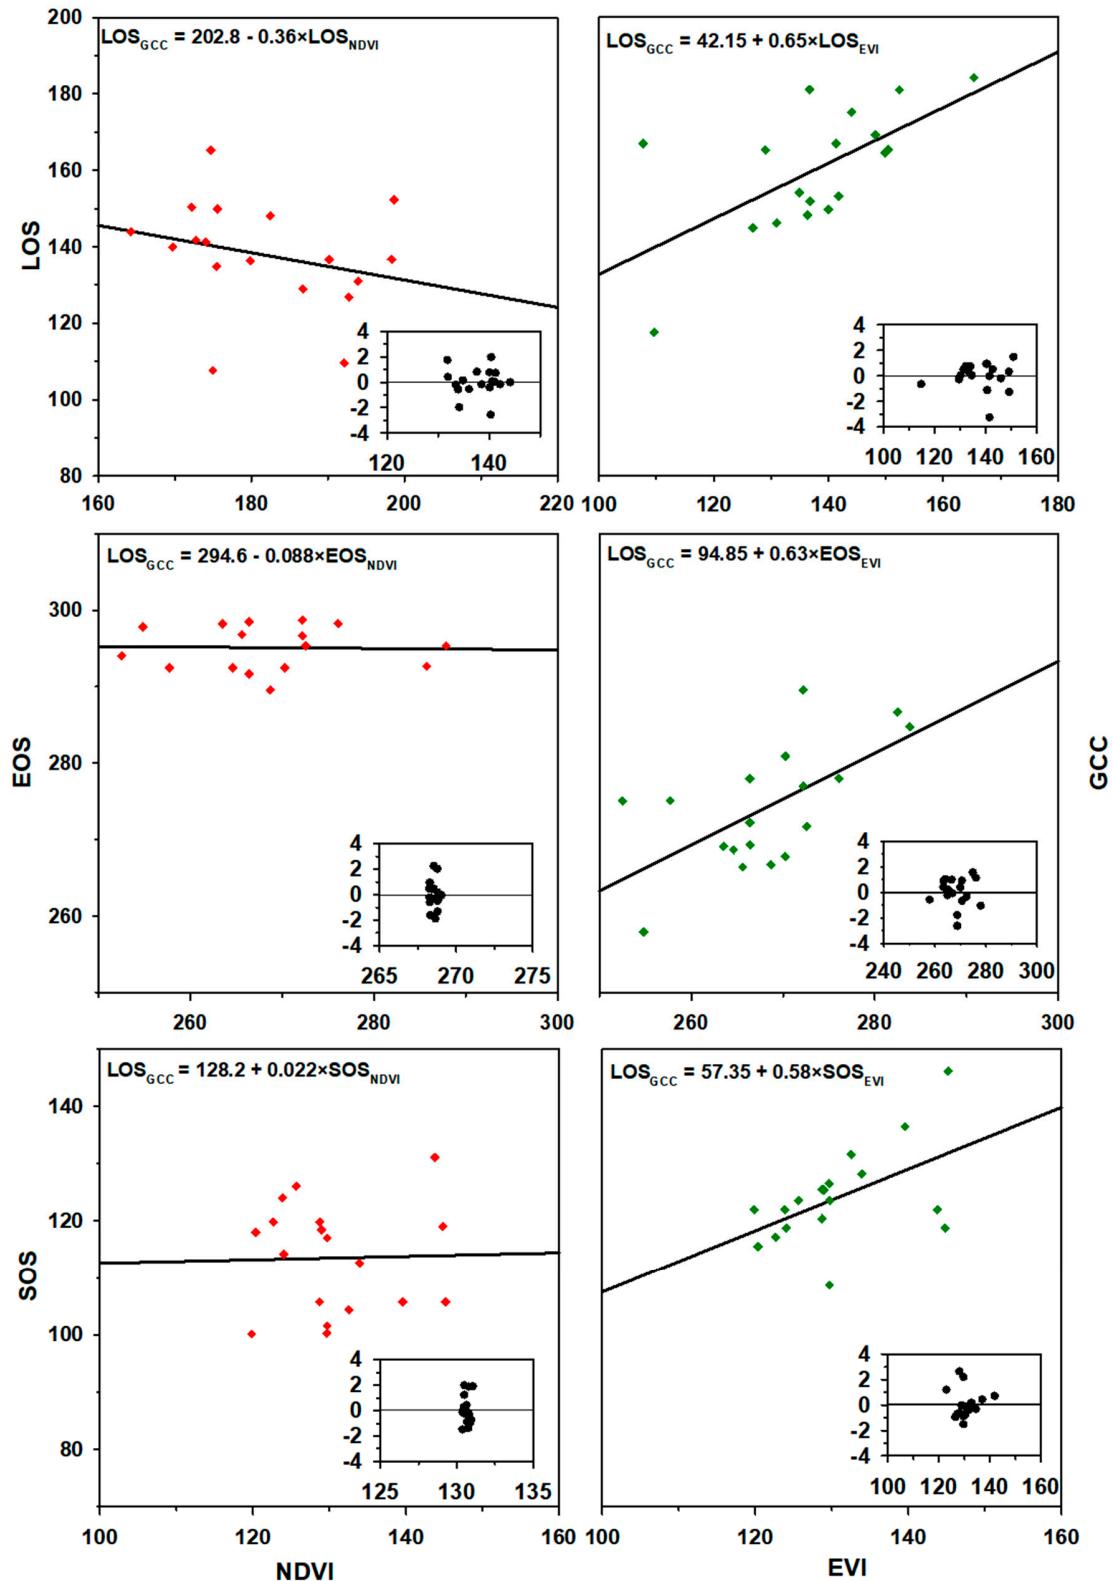

Table S1. Coefficients of the double-logistic function fitted for the GCC of black spruce during 2016, 2017, 2018 and 2019 for six sites along the latitude in Quebec.
