Abstract: The aim of this study was to analyze the mid-term influence of minimum tillage (MT) combined with early leaf removal (ELR) on the performance of the black grapevine variety Nerello Mascalese (*Vitis vinifera* L.). The research was carried out from 2015 to 2018 in a vineyard located in the Mount Etna area, East Sicily, Southern Italy. An average of about 8000 cm² of leaves were removed from the ELR vines, corresponding to a canopy defoliation of 44% in 2017 and 30% in 2018. As for the stem water potential of both primary and lateral leaves, ELR-MT treatment showed the best performance (up to −0.4 MPa) among the four combinations. In 2017, no differences in yield/vine were found among treatments, whereas in 2018 the yield was significantly lower in ELR treatments. Among the different treatments performed, the ELR-MT showed the best results both in terms of physiological plant parameters (water status and photosynthetic activity) and fruit quality (higher concentration of sugars and total anthocyanins and polyphenols). ELR-MT treatment is also associated with a lower incidence of tillage operations from four to only one per year (−60–70 h/ha). In contrast to what was observed in the first 3 years of application (i.e., from 2015 to 2017), yield was heavily penalized during the fourth year of application (2018), probably due to the excessive depletion of nutritional reserves, the reduction of bud fertility and the unfavorable meteorological condition. For these reasons, the ELR-MT combination might require an interruption every 2–3 years of application.

Keywords: vineyard; early leaf removal; soil tillage; water potential; photosynthesis

1. Introduction

The Etna area (East Sicily, Southern Italy) is characterized by a wide variety of microclimate and soil composition; such environmental characteristics, coupled with adequate management practices, have a strong impact on grape and wine properties. The soil in which vineyards are planted is strongly influenced by the proximity to an active volcano and is basically sandy, well-drained, poor in fertility and subjected to water scarcity during the summer [1]. At present, for its sustainability and to ensure optimal must composition, grape production requires the application of both conservative soil practices and the use of effective canopy management strategies.

The increasing interest in the quality of wine production (e.g., terroirs) and the need of coupling wine-making with sustainable practices capable of maintaining or improving

the soil fertility—mostly in the mountain areas [2]—are important aspects for the set-up of novel implants.

Generally, conventional soil management practices include three to four mechanical tillages per year for weed control or herbicide application. In addition, farmers usually increase the use of fertilizer to intensify vine growth and yield, with a corresponding enhancement of cost and pollution [3]. In contrast, conservative soil management practices such as zero or minimum tillage reduce erosion rates and moisture losses and increase organic matter content [4,5], with a positive effect on the yield and fruit quality traits [6]. Moreover, conservative soil management reduces the energetic costs [7,8] related to field maintenance, and have beneficial effects on root growth, resulting in an improved soil volume explored by the plants [9,10]. Among the conservative practices (i.e., zero tillage, minimum tillage, mulch tillage and cover crops [11]), minimum tillage is a valid alternative to conventional tillage to control weed competition, vine vigor and bud fertility [6], avoiding the excessive water consumption observed with other techniques, such as the use of cover crops [12]. Compared to conventional tillage, the conservative soil strategies minimize the soil disturbance in terms of depth and till frequency, determining an increase in the storage of organic matter compared to conventionally tilled soils [13]. Generally, in conservative tillage systems (i.e., zero and minimum) the soil density in the untilled layers increases, but a greater biological density of the untilled layer may be counterbalanced by an increase in biological macroporosity and pore continuity [14].

Vine performance also depends on the agronomic practices related to the canopy control. Among these, leaf removal performed at an early stage of plant development (before bloom) represents an important tool for vine management, through a modification of the source–sink relationships [15–19]. In fact, a recent meta-analysis review reports that this management practice has an effect in the reduction of fruit yield and in the control of bunch rot disease. At the same time, leaf removal also has a positive effect on the accumulation of sugar, anthocyanins and polyphenols, mainly due to the increase in the leaf-to-fruit ratio [20]. Moreover, pre-bloom leaf removal could be of interest for vineyards in mountain areas and when late-ripening cultivars are used, especially determining a better canopy aeration and allowing a better control of fungal diseases. In this study we analyze the mid-term influence of minimum tillage combined with early leaf removal on the productive behavior and physiology on the autochthonous black grape cv. Nerello Mascalese.

2. Materials and Methods

2.1. Site, Plant Material, Environment, and Experimental Design

The research was carried out in a rainfed vineyard located on the Etna volcano (lat. 37°41'13" N; long. 15°07'00" E; elevation 602 m a.s.l., eastern-facing slope). Vines (*Vitis vinifera* L.) cv. Nerello Mascalese, grafted onto 140 Ru rootstock, were planted in 2010, in rows orientated ENE–WSW, spaced 2.5 m between rows and 1.2 m within rows. Vines were trained using a vertical-shoot positioned, spur-pruned permanent cordon at 0.7 m from the soil and the top of the canopy at approximately 1.80 m. Vines were spur-pruned from six to eight nodes per vine (two nodes per spur and three to four spurs per vine).

Two soil management schemes and two canopy management treatments were arranged in a factorial combination to conduct the trial over four consecutive growing seasons, from 15 June 2015 to 30 January 2019. Here we present data from 2017 to 2018.

2.2. Climate and Soil

The climate of the trial site is reported in [18], where the monthly minimum, mean and maximum solar radiation; air temperature and rainfall in the experimental vineyard were registered (Figure 1). According to the USDA scheme [21], the soil is classified as loamy-sandy, as reported in a previous study performed on the same site [22].

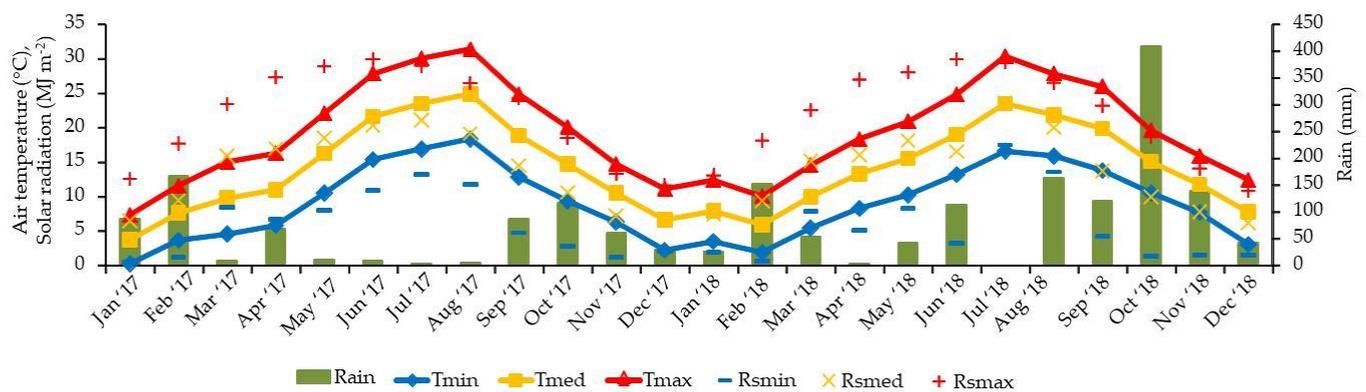

Figure 1. Monthly minimum (Rsmín), mean (Rsméd) and maximum (Rsmáx) global radiation (MJ m^{-2}); minimum (Tmín), mean (Tavg) and maximum (Tmáx) air temperature ($^{\circ}\text{C}$) and total rainfall (mm) in the vineyard (lat. $37^{\circ}41'13''$ N; long. $15^{\circ}07'00''$ E; elevation 602 m a.s.l.) in 2017 and 2018.

2.3. Vineyard Soil Management

Two soil management schemes were compared: (i) minimum tillage (MT) and (ii) conventional tillage (CT). The MT treatment included just one mechanical tillage (15 cm deep) in mid-April. Meanwhile, CT included three mechanical tillages per year, at the end of January (25 cm deep), in mid-April (15 cm deep) and in early July (10 cm deep).

2.4. Vines Canopy Management

Two canopy management practices were compared: (i) removal of all basal leaves on all shoots up to the leaf upper the last cluster (ELR: early leaf removal); (ii) no leaf removal (NLR). Each year, primary and lateral leaves were removed by hand at phenological growth stage BBCH61 (beginning of flowering: 10% of flowerhoods fallen) [23]. At this stage, on five vines per treatment, the area of remaining and removed leaves from primary and lateral shoots and the length of primary and lateral shoots were measured. The area of removed leaves was determined using an area meter (model LI-3100; Licor, Inc., Lincoln, Nebraska). The total leaf area per vine, the removed leaf area per vine (independently from primary and lateral shoot) and their percentage incidence were calculated.

2.5. Combined Treatments

The four combined treatments analyzed were: (1) Early Leaf Removal—Minimum Tillage (ELR-MT), (2) No Leaf Removal—Minimum Tillage (NLR-MT), (3) Early Leaf Removal—Conventional Tillage (ELR-CT), (4) No Leaf Removal—Conventional Tillage (NLR-CT).

2.6. Experimental Design

Three independent blocks were used, each consisting of 12 rows containing 60 vines each. The four combined treatments were applied on three rows inside each block. All measurements were made on five vines per treatment per block, selected in the central part of the rows.

2.7. Physiological Measurements

Midday stem water potential was measured by a Schöelander pressure chamber (Soil Moisture Equipment Corp., Sta. Barbara, CA, USA) according to [24]. Leaves were closed into a black hermetic plastic bag covered with an aluminum foil for at least 2 h before detachment from the vine and measurement. Net photosynthesis (Pn) and transpiration (E) rates of well-exposed, fully expanded leaves from primary and lateral shoots were measured with a portable infrared gas analyzer LI-6400 (Li-Cor, Lincoln, NE, USA). All measurements were made each year from DOY 181 (30 June) to DOY 241 (29 August) every

15 days from 12:00 p.m. to 1:30 p.m. For each treatment and date of measurement, data were collected from five fully exposed primary leaves and five lateral leaves.

2.8. Vine Yield and Grape Composition

In 2017 and 2018, yield per vine and grape composition were analyzed at harvest, which occurred on 15 and 29 September, respectively. Grapes were harvested when they reached optimal commercial maturity, according to the needs of the winery. Bunches were collected from 5 vines per treatment on each block to determine the yield assessment. A sample of five bunches per treatment on each block (15 bunches per treatment) was used to determine the bunch weight and the number and weight of berry. A 100-berry sample per experimental block was divided in three sub-samples, crushed with a manual press and free-run juice utilized to determine the total soluble solids (TSS) with a digital refractometer with temperature correction (RX-5000 Atago Co., Ltd., Bellevue, WA, USA), must pH and titratable acidity (TA), using an automatic titrator (Titrino model 798, Metrohm, Riverview, FL, USA) with 5.0 mL juice samples being titrated against 0.1 M NaOH to pH 8.2; TA was expressed as g/L of tartaric acid equivalents. The total polyphenol content was determined using the Folin–Ciocalteu reagent assay [25,26] and expressed as mg/kg of grapes. Total anthocyanins were expressed as mg/kg of fresh weight as reported by [27].

2.9. Statistical Analysis

Analysis of variance (ANOVA) was performed with Jamovi 1.2 statistical software [28]. One-way ANOVA was carried out on physiological and qualitative/productive traits to assess the effect of each treatment within each year, ANOVA was used to assess the differences among the soil and canopy treatments among the years and repeated measures ANOVA was performed to individuate differences between the two years of treatment at specific days of the year. A post-hoc analysis based on Tukey HSD test (Tukey honest significant differences) was performed at significance levels (p -value) of 0.05, 0.01 and 0.001.

3. Results

3.1. Climate Variables

The biannual average temperature was 14.2 °C (Figure 1). During the study, the lowest minimum temperatures were recorded in January 2017 and February 2018. The warmest months in 2017 were July and August (daily mean temperature above 23 °C) and July in 2018. However, the degree days available were about 1545 GDD from bud burst to harvest in 2017 and 1563 GDD in 2018 (Figure 1). The growing degree days, calculated as $\sum T_{\text{mean}} - 10$ (value 10 is the base threshold temperature), were used to estimate the growth and development of vines during the growing season. Annual rainfall was about 650 mm in 2017 and 1250 mm in 2018. The driest month was July in both years (only 4.8 mm in 2017 and 0.6 mm in 2018); the rainfalls registered in August were 6.8 mm and 163.8 mm in 2017 and 2018 respectively, while rainfalls in September were 86.8 mm in 2017 and 120.8 mm in 2018. Even if after the harvest, it is interesting to note the extremely high amount of precipitation in October 2018, reaching 409.2 mm.

3.2. Leaf Removal Intensity

In 2017 and 2018, an average of 8000 cm² of leaves were removed from ELR vines corresponding to a canopy mean defoliation of about 44% in 2017 and 31% in 2018 (Table 1). Moreover, in 2018 compared to 2017, a significant decrease in the leaf area removed from primary shoot was registered: 53% in ELR-MT and 50% in ELR-CT.

Table 1. Impact of leaf removal on primary and lateral shoot leaf area and length in 2017 and 2018 seasons in the following combination: Early Leaf Removal-Minimum Tillage (ELR-MT) and Early Leaf Removal-Conventional Tillage (ELR-CT). Data are means \pm standard deviations. Means for each year indicated by different letters are significantly different ($p \leq 0.001$) based on Tukey's HSD post hoc test within treatments.

Parameters	2017		2018

<i>p</i> -Level		**		n.s.

For each year, interactions are indicated by: * Significant $p < 0.05$; ** Significant $p < 0.01$, based on Tukey's HSD test (\pm standard deviation). n.s. = not significant.

3.3. Physiological Measurements

Concerning the stem water potential, in 2017 the ELR-MT treatment showed the best performance in both primary and lateral shoots, showing less-negative values at each date (Figure 2). However, similar results were reached by all the treatments at DOY 196 and 211 for the main shoots and at DOY 211 for the lateral shoots. NLR-MT showed the worst stem water potential values for both primary and lateral shoots at DOY 226 in 2017 and in primary shoots at DOY 211 in 2018, when the hottest temperatures were reached. CT also negatively affected the stem water potential (about 10% more negative than MT), but the ELR effect was positive, reducing vines' stress (i.e., the mean values in ELR vines were about 10% higher than in the NLR ones).

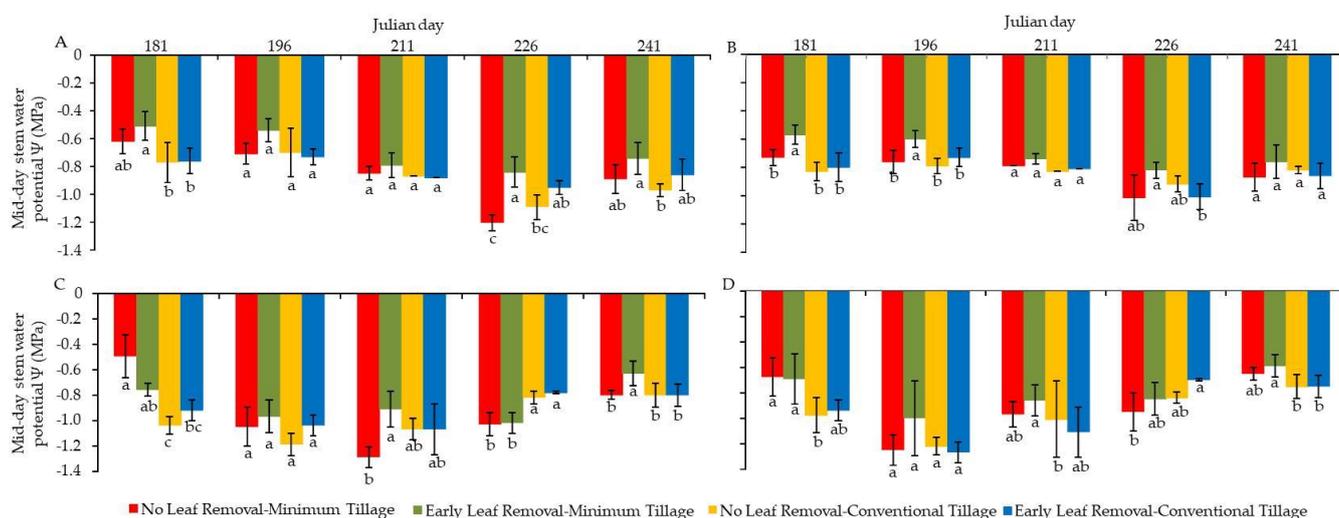

Figure 2. Mid-day stem water potential measured in 2017 ((A) primary leaves, (B) lateral leaves) and 2018 ((C) primary leaves, (D) lateral leaves) for the four combinations analyzed. For each year, treatment and day of the year, the values marked by different letters are significantly different ($p \leq 0.05$) based on Tukey's HSD test (bars indicate \pm standard deviations).

The hottest months of 2017 were July and August, both characterized by a lack of rain (only 4.8 mm and 6.8 mm, respectively) and higher air temperatures. In all treatments, the greatest vine stress, both in primary and lateral shoots, was detected at DOY 226 (Figure 2A,B; Supplementary Material, Tables S1 and S2). In 2018, the hottest and most

arid month was July, with only 0.6 mm of rain, and the highest water stress was generally registered in the leaves of primary shoots on DOY 211 (stem water potential up to -1.3 MPa) and in the leaves of lateral shoots mostly on DOY 196 (Supplementary Material, Tables S1 and S2). In August 2018, the rainfall reached 165 mm and the average air temperature was lower than 2017 (about -1.53 °C) and the treatment ELR-MT confirmed the lowest values of water stress at DOY 211 and 241 both for primary and lateral shoots (Figure 2C,D). The effects of soil management and leaf removal in 2018 showed opposite results, and ELR confirmed its effectiveness in improving the stem water potential. Regardless of tillage, the NLR had the lowest stem water potential in mid-summer.

In 2017, the Pn rate in both primary and lateral leaves of ELR-MT vines was higher during July and August (Figure 3A,B), according to the optimal values of stem water potential (Figure 2). At DOY 226 and 241 the MT vines had significantly higher values of Pn compared to CT treatments, especially in the leaves of primary shoots, with values almost doubled (from 6 to 12 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$). In 2018, soil management determined fluctuating values of Pn in the leaves of both primary and lateral shoots; however, the positive effect of MT on Pn can be estimated as about 30% (Figure 3C,D). In 2017, Pn and E rates in ELR-MT exhibited an opposite trend (Figures 3 and 4), suggesting that in this case the water availability was not a limiting factor for the assimilation process. On the contrary, for all the other treatments this statement cannot be confirmed due to a strong variability in both physiological parameters. The year 2018 was characterized by a concentration of rain both in June (115 mm) and in August (164 mm), and this positively influenced the Pn at DOY 181 and 226 in MT treatments. While at DOY 226 the Pn values were similar to those of the previous year, at DOY 181 MT treatments (ELR-MT and NLR-MT) increased their values (almost +50% for both treatments). This could be due to a more efficient use of water resources, especially from young leaves, or to a higher water content into the soil.

The main effects of Year (Y), DOY (D), Canopy (C) and Tillage (T) on physiological parameters are reported in Table 2. All the factors analyzed significantly influenced all the parameters, with the exception of Y, which did not affect transpiration rates on lateral shoots, and T, which did not affect the transpiration rates of either primary or lateral shoots. Among the interactions between factors, the most significant were $Y \times D$ and $D \times T$, and as a direct consequence of these interactions, $Y \times D \times T$ showed the same significance.

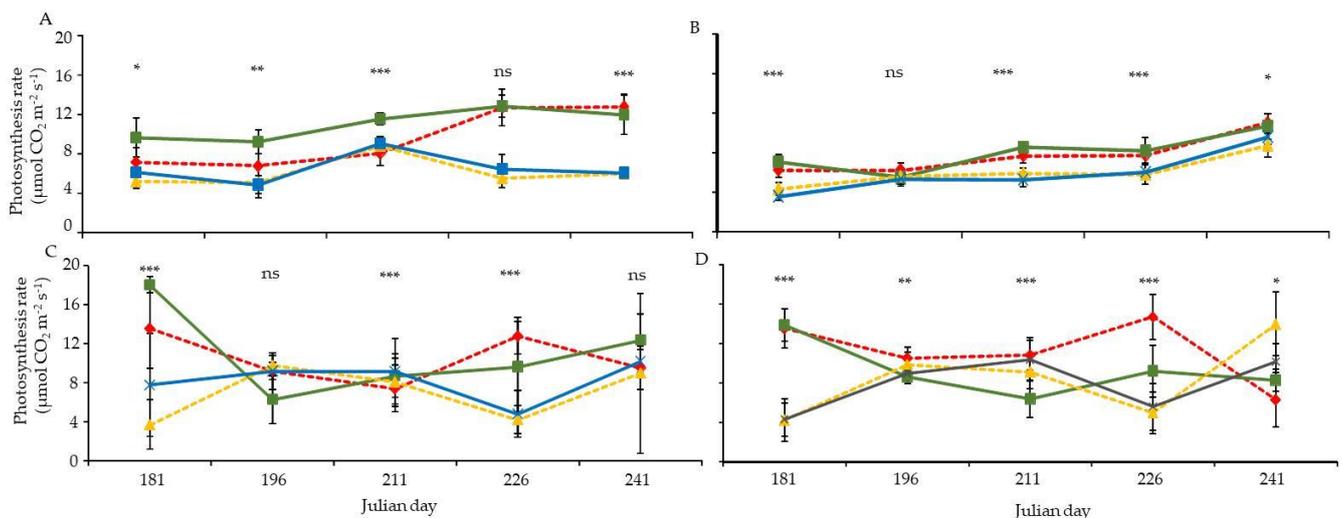

Figure 3. Net photosynthesis measured in 2017 ((A) primary leaves, (B) lateral leaves) and 2018 ((C) primary leaves, (D) lateral leaves) for the four combinations analyzed. For each year, *, ** and *** represent significant differences at $p < 0.05$, 0.01 and 0.001, respectively, and ns indicates no significant difference, based on Tukey's HSD test (\pm standard deviation).

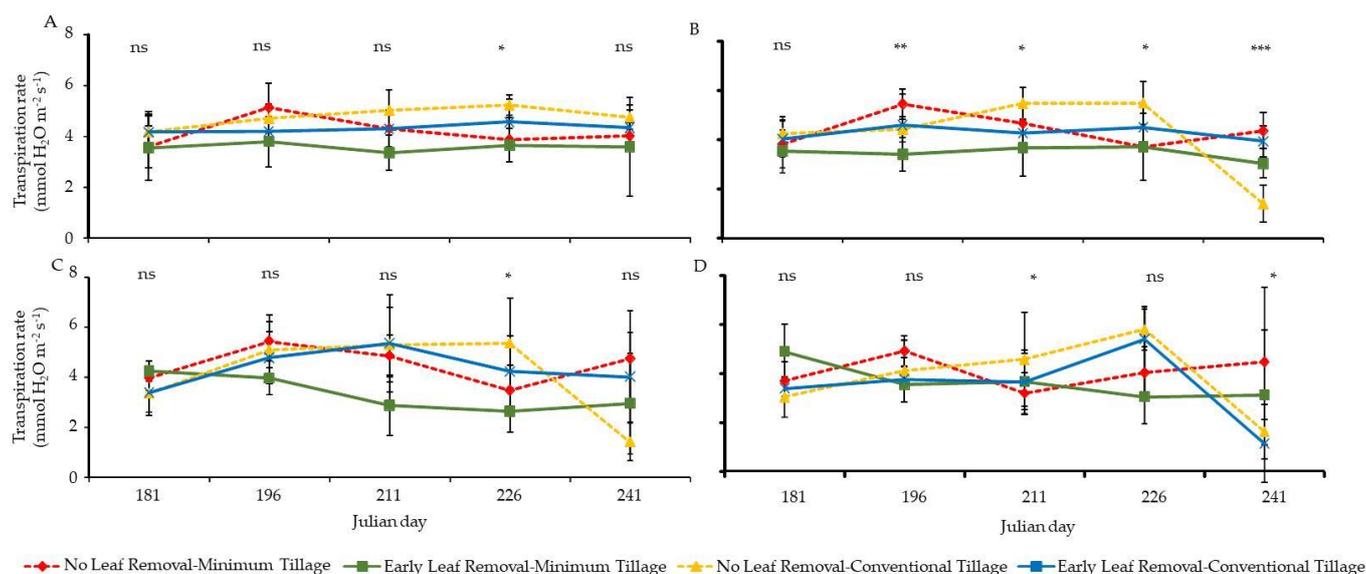

Figure 4. Transpiration rate measured in 2017 ((A) primary leaves, (B) lateral leaves) and 2018 ((C) primary leaves, (D) lateral leaves) for the four combinations analyzed. For each year, *, ** and *** represent significant differences at $p < 0.05$, 0.01 and 0.001 , respectively, and ns indicates no significant difference, based on Tukey's HSD test (\pm standard deviation).

3.4. Yield and Grape Composition at Harvest

In 2017, no difference in yield per vine was found between treatments, nor for bunch and berry weight or number of berries per bunch (Table 3). In 2018, the yield per vine was significantly lower in ELR-MT (-24% in comparison to NLR-MT) and in ELR-CT (-38% in comparison to NLR-CT) due to reductions of both the bunch weight and the number of berries per bunch (Table 3). In 2017, the combination ELR-MT determined a higher TSS accumulation in the grapes ($+1.9$ °Brix) compared to NLR-MT, and improved the content of anthocyanins ($+29\%$) and polyphenols ($+10\%$) (Table 3). The anthocyanins/TSS ratio was also increased in the grapes from ELR-MT vines ($3.88 \text{ mg kg}^{-1} / \text{°Brix}$ versus an average of 3.36 found in the other three treatments). Moreover, the grape ripening in the ELR-MT treatment was earlier, as shown by AT values of 0.77 g/L against an average of 0.95 g/L found in the other three treatments.

In 2018, no significant differences were found in TSS, TA and must pH among treatments, whereas in the ELR-MT vines the total content of anthocyanins and polyphenols increased in comparison to NLR-MT ($+44\%$ and $+75\%$, respectively) (Table 3). Similar to what was found in 2017, in 2018 the MT treatment also increased the anthocyanins/TSS ratio by about 35% in the grapes from ELR vines and by 46% in NLR vines.

As shown in Table 4, among the factors evaluated in the trial (Year (Y), Canopy (C) and Tillage (T)), the weather trends of the years (Y factor) influenced most of the parameters, except for TA, total polyphenols and total anthocyanins/TSS ratio. On the contrary, none of the interactions between factors revealed any significance concerning the pomological parameters, while among the qualitative parameters only TSS ($Y \times T$ and $C \times T$) and TA ($Y \times C$ and $Y \times T$) registered a significant effect.

4. Discussion

Nerello Mascalese is one of the traditional grape varieties in the Etna area, and in recent decades it registered an increased interest due to its use for wine making. This variety is characterized by high acidity and low anthocyanins accumulation; moreover, the acylated derivatives are very scarce (lower than 1% of the total). Therefore, the resulting wine can be poor of color and sometimes difficult to age [29]. These defects increase in years characterized by either frequent rains and cool summers, or by excessive drought. In these situations, canopy and soil management techniques regulating the microclimate of fruit zone and vine physiology may improve the evolution of grape ripening. This study was conducted in an area that is often characterized by a rainy period starting from October until March, and a dry period from the last days of the spring until the end of summer, in which rains may occur in the last phases of grape ripening, increasing the incidence and severity of rots. Soils are extremely sandy, deep and often with a high skeleton content [6]. Vineyards are not irrigated, and therefore water stress may be frequent due to the low soil water retention and the paucity of mid-summer precipitation. In the studied area, soil management is still commonly carried out by mechanical tillage (three/four times per year with a need of more than 100 h of labor per hectare), while canopy defoliation is performed in the last stages of bunch ripening in order to improve light interception and grape composition and prevent fungal diseases. Many studies in recent years have focused on the effects of early defoliation and canopy management on the yield and quality aspects of grapes [30–33], and on the benefits of conservative tillage in order to reduce organic matter loss and erosion rates and increase moisture retention in the soils [2,4,34]. In previous research, we analyzed—in different climate areas and both in rainfed and irrigated vineyards—the influence of early leaf removal, identifying benefits in terms of yield traits and disease control [17–27]. Koblet et al. [35] reported a yield decrease as a consequence of vine defoliation due to a decrease in cluster weight following a reduction in berry weight. The registered differences concerning the TSS in the ELR-MT treatment were due to a higher and extended sunlight exposure of the grapes. This condition might positively impact cellular growth in the berry, counteracting carbohydrate limitations [33]. Regarding soil management, is important to highlight that the vineyard is located in an area which has a highly seasonal rainfall pattern and a dry period which corresponds with the phenological stages of late flowering, berry set, veràison and ripening. Here the soil and atmospheric water deficits, in combination with high air temperatures, exert complex effects on fruit yield and berry composition [36]. In the study area, these conditions are particularly limiting because of the soil’s physical characteristics, and because of its low content of organic matter—especially on the east-facing slopes. The yield reduction in 2018 probably depended not only on the LR treatment but also the MT treatment. Our

results agree with Lopes et al. [37], who reported an increase of competition between vines and weeds (cover crops) for water that resulted in significant yield reductions. On the contrary, Monteiro and Lopes [12] reported that conservation tillage did not affect yield. We aimed to understand how the combination of both soil and canopy management practices could affect vine physiology, yield and grape composition. In our study, after three consecutive seasons of application, the ELR technique (irrespective of soil tillage) lowered bunch weight as a consequence of fruit-set reduction and therefore a lower number of berries per bunch, and was responsible for the significant yield reduction in 2018. On the other hand, Lebon et al. [38] reported that carbohydrates depression due to leaf removal before flowering exerts a negative impact on sugar flow, the meiosis process in flowers and finally in the bud fertility. This behavior could be responsible for an increase of the vegetative/reproductive balance, notwithstanding the increase not in the number of leaves or their total area, but in shoot length in CT treatments. In fact, in these treatments, the percentage of the removed leaf area was lower in 2018 than in 2017. This difference resulted from a restriction of the area of interest to the defoliation in the whole canopy, meaning that the fruiting shoots of the CT vines reduced the distal bud fertility. This behavior was probably due to an increase of the vegetative activity of the CT vines over the years, causing a modification of the reproductive and vegetative balance. However, this effect could be exploited for highly vigorous cultivars characterized by big and compact bunches to reduce yield and obtain looser bunches. This could also be considered as a tool in the controlled 'designation of origin' areas to maintain the yield per hectare within the imposed limits. However, for the low-vigor cultivars and for the conditions of this trial, the yield reduction obtained must be considered as a negative result. However, next to the diminished yield found in 2018, in general the ELR treatment exerted a positive effect on TSS accumulation, and in 2017 also caused a fast reduction of TA, showing an earlier grape ripening. In ELR treatment, the soil management did not modify yield and grape composition in 2017, whereas in 2018 when matched with MT treatment the TSS, anthocyanins and polyphenols content significantly increased in comparison to CT. This coupled treatment could be taken into account, but it is important to consider that the above-mentioned results, found in 2018, were probably also due to the drastic reduction in yield per vine recorded in that year. The analysis of the factors Year (Y), Canopy (C) and Tillage (T) in interaction showed that the most influencing factor on the pomological parameters was the Y. However, this factor alone was not able to significantly influence some of the qualitative parameters (TA, Total polyphenols, Total anthocyanins/TSS). Canopy and tillage management were efficient for the modification of the TSS and TA. These parameters are those mainly considered by winegrowers for cellar operations. Therefore, the validity and economic convenience of the coupled treatment ELR-MT for consecutive years is cultivar- and site-dependent. Interestingly, in both years and irrespective of leaf removal, the MT increased the anthocyanins/TSS ratio compared to CT by about 20% in 2017 and 40% in 2018, on average. Therefore, considering the reduction of about 60–70% of the labor needs for soil management, MT treatment could be a valid strategy in comparison to CT, especially when matched with ELR.

Each factor analyzed (Y, D, C and T) showed a strong influence on almost all the physiological parameters considered. Among the interactions, $Y \times D$ and $D \times T$ showed the strongest impact on all the parameters, meaning that the two years had a totally different impact on the vines thanks to the different meteorological trends during the two summer seasons. In any case, for each season, T treatment was a strong influencing factor for vines' physiological responses. The interaction $C \times T$ was less impactful on the vines' performances, and for the two years considered ($Y \times C$). As expected, when NLR was paired with MT treatment, the values of stem water potential increased (up to -1.3 MPa). This fact highlights that MT plays a positive role in water retention in the upper layers of soil in which roots may grow undisturbed [39], but the development of more weeds and higher total leaf area per vine can determine a higher water requirement.

Despite the fact that 445 mm of rain were registered from April to September in 2018 (+285 mm compared to 2017), a reduction in both leaf area and yield per vine was observed in comparison to 2017, with the exception for total leaf area in the ELR-MT treatment. These behaviors are probably related to a decrement of the replenishment of reserves in storage organs during the previous three years of ELR application (i.e., from 2015 to 2017), leading to a negative effect on bud fertility. For these reasons, the combined treatment ELR-MT requires an interruption every 2–3 consecutive years of application.

5. Conclusions

The proposed integrated agronomic practices concerning the soil (minimum tillage vs. conventional tillage) and the canopy (early leaf removal vs. no leaf removal) management may represent a valid tool to improve grape composition and maintain good yield. In the combined ELR-MT strategy, yield per vine was not compromised during the consecutive 2–3 years of application, whereas in 2018 (fourth year of application) it was strongly penalized, probably due to excessive depletion of nutritional reserves, reducing bud fertility, as well as unfavorable climate conditions. For all these reasons, the combination treatment ELR-MT must be interrupted every 2–3 years of application. Moreover, the combination ELR-MT in the autochthonous Nerello Mascalese black cultivar gave the most efficient outcome at a physiological level, maintaining a better water status and photosynthetic activity, ensuring a higher concentration of sugars and total anthocyanins and polyphenols in the grapes, in addition to saving the labor needed for conventional management.
