Abstract: In Portugal, the Cova da Beira region is well-known for the production of *Prunus* spp. and is considered the main peach production area in the country. In the spring of 2021 and 2022, field surveys in peach and nectarine orchards showed symptoms of decline such as cankers, gummosis, dry branches, abortion of flowers, mummified fruits and the partial or total death of some plants. Brown rot is caused by three species of the genus *Monilinia*, *M. fructigena*, *M. laxa* and *M. fructicola*, the last is an OEPP/EPPO A2 quarantine organism on peach trees. Brown rot disease had previously been described in the Cova da Beira region, however, the recent high mortality and severity of symptoms raised doubts as to the species involved. Symptomatic plant material was collected from thirteen orchards and used for fungal isolation and molecular detection according to the OEPP/EPPO standard. *M. fructicola* was confirmed morphologically and molecularly in two orchards, and molecularly (duplex real-time PCR) detected in two others. Whole genome sequencing using Oxford Nanopore MinION was also carried out to confirm the identification. Pathogenicity tests were performed on peach, nectarine and sweet cherry fruit according to Koch's postulates. Based on all the results obtained, we report the first detection of *M. fructicola* in *P. persica* in Portugal.

Keywords: brown rot; Cova da Beira; first report; whole genome sequence; pathogenicity tests

1. Introduction

Peach (*Prunus persica* (L.) Batsch) is a deciduous tree cultivated in temperate and subtropical regions [1], belonging to the Rosaceae family, and one of the most important fruit crops in the world [2]. According to the latest available data published by the Food and Agriculture Organization (FAO), the production of peaches and nectarines in Europe reached 3,219,958.62 tonnes, making it the second largest producer in the world, surpassed only by China [1]. In Portugal, the main production area for peaches and nectarines is located in the Cova da Beira region. According to Portuguese statistics, the production of peaches and nectarines (*Prunus persica* var. *nucipersica*) reached 34.776 tonnes, of which, 18.706 tonnes were produced in central Portugal [3]. However, this fruit sector is vulnerable to several pre-harvest and post-harvest diseases [4]. Brown rot is one of the most economically important and destructive diseases in stone fruits, especially in peaches [5]. The causal agents are three related pathogens, *Monilinia fructigena*, *M. laxa*, and *M. fructicola* [6], classified by the European and Mediterranean Plant Protection Organization (EPPO) as an A2 pest for peach crops [7].

M. fructicola has been detected in North and South America, Australia, and Japan [8]. In Europe, it was first detected in peach orchards in France [9]. Since 2001, the disease has spread to many European countries and has been found on stone fruits in Hungary, Spain, Slovenia, the Czech Republic, Italy, Serbia, Croatia and Bulgaria [10–16].

Flowers, twigs, leaves, and fruits are the main plant parts affected by these pathogens. The most common symptom is the rotting of mature fruits, the infected fruits may remain mummified and attached to the tree, which is important for the survival of the pathogen over seasons [7]. Flower necrosis with gummosis is also a symptom, on twigs, symptoms appear as cankers and leaves on affected shoots wilt and remain attached to the branch. *Monilinia* species are difficult to distinguish, and molecular methods such as conventional polymerase chain reaction (PCR) or real-time PCR are important for accurate identification.

Symptoms such as damaged blossoms, flowers abortion, gummosis, mummified fruits attached to the tree, and the total or partial death of some plants were observed in situ during the field surveys carried out in the spring of 2021 and 2022 in peach and nectarine orchards in Cova da Beira. These symptoms are typical of brown rot, some of which have been reported in Portugal, but these were attributed to the presence of the less destructive species of *Monilinia* sp. (e.g., *M. laxa* or *M. fructigena*) [17]. The severe decline associated with partial or total plant death raises the question of which *Monilinia* species caused this outbreak. The aim of this work was, therefore, to identify the causal agent responsible for the decline in *P. persica*.

2. Materials and Methods

2.1. Sample Collection

Symptomatic flowers and branches were collected from 42 trees distributed in 13 orchards in Cova da Beira, stored in sterile plastic bags at 4 °C and processed within 24 h (Table 1). Branches and flowers from each tree were processed independently.

2.2. Isolation of Putative *M. fructicola*, Morphological Identification

Symptomatic branch segments from 42 trees were sterilized as previously described by Eevers et al. [18] and plated on potato dextrose agar (PDA) media supplemented with streptomycin (0.5 g/L) to prevent bacterial growth, followed by incubation at 22 °C in the dark for 7 days. The presumptive morphological identification of *Monilinia* sp. was based on the microscopic structure of the lemon-shaped conidial chains, observed after staining with lactophenol cotton blue [7] and further confirmed by molecular assays (Section 2.3).

2.3. DNA Extraction from Single Colony and Molecular Identification by PCR

DNA extraction of four putative *Monilinia* sp. isolates based on morphological structures was performed after 7 days of mycelial growth using the REExtract-N-Amp™ Plant PCR kit (Sigma Aldrich, St. Louis, MI, USA). PCR was performed as previously described by White et al. [19] to amplify the internal transcribed spacer (ITS) region of all isolates, using primers ITS1 (5'-TCCGTAGGTGAACCTGCG-3') and ITS4 (5'-TCCTCCGCTTATTGATATGC-3'). The resulting amplified fragments were purified using the NZYGelpure Kit (NZYTech™, Lisbon, Portugal) and sequenced with the ITS4 (5'-TCCTCCGCTTATTGATATGC-3') standard sequencing primer at STABVIDA, Caparica, Portugal. For molecular identification, the sequences obtained were processed using Geneious® 10.2.2 software and compared with sequences available in the National Center for Biotechnology Information (NCBI) using BLAST [20]. To further confirm the identity of the isolates, ITS sequences of closely related reference *Monilinia* species were downloaded from NCBI and studied through phylogenetic methods. The sequences were aligned using the online version of MAFFT v.7 [21] and manually adjusted using UGENE v.1.26.3 [22]. Maximum likelihood analysis was then performed using MEGA11 [23] with the K2+G substitution model and 1000 bootstrap replicates to verify the branches.

Table 1. Characterization of sampled plant material and methods used to detect *Monilinia fructicola* (X).

| | | 2 | branch | | | | x |

2.4. Total DNA Extraction from Branches and Flower Extracts

Symptomatic branch segments and flowers collected from 42 trees (Table I) were placed in a Bioreba bag containing 5 mL phosphate-buffered saline (PBS) and macerated using a homog-

enizer (Homex 7, Bioreba, Reinach, Switzerland). Total DNA was extracted using the Dneasy Plant Kit (Qiagen, Venlo, The Netherlands) according to the manufacturer's instructions.

2.5. Molecular Identification by Using Real-Time PCR

A duplex real-time PCR developed by Van Brouwershaven et al. [24] and according to EPPO standards [7], was used to identify *Monilinia* sp. in all plant extracts (Table 1). This protocol distinguishes *M. fructicola* from *M. fructigena* and *M. laxa*. Positive controls for *M. fructicola* CECT 21105, *M. fructigena* CECT 21206, and *M. laxa* CECT 21100 were obtained from the University of Valencia.

2.6. Pathogenicity Test

Pathogenicity was confirmed by inoculating surface-sterilized 12 peaches, 12 nectarines, and 24 sweet cherries (*Prunus avium* L.) with mycelial plugs of *M. fructicola* isolate 160E. Three-millimetre plugs were taken from a 7-day-old culture and placed upside down on the fruits, which had previously been wounded with a three-millimetre cork borer, in three replicates were made for each fruit type. Control fruits for each treatment were inoculated with sterile plugs of PDA. Fruits were kept in a humid chamber at 22°C for 7 days throughout the experiment. The pathogen was re-isolated from the inoculated fruits, grown on PDA and molecularly identified by real-time PCR (Section 2.5), as previously described.

2.7. Genome Sequencing, Assembly, Annotation, and Functional Analysis

Genomic DNA from isolate 160E was purified according to the protocol of the MasterPure™ Complete DNA & RNA Purification Kit (LUCIGEN, Biosearch Technologies, Hoddesdon, UK). DNA quality and concentration were assessed using a NanoDrop 2000C spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA) and a Qubit 2.0 fluorometer (Life Technologies, Carlsbad, CA, USA). MinION whole genome sequencing was performed by preparing a genomic library using the ligation sequencing kit (SQK-LSK109, Oxford Nanopore Technologies (ONT), Oxford, UK), according to the manufacturer's protocol. The library was then loaded onto a flow cell (R9.4.1, FLO-MIN106), and sequenced for 15 h and 41 min. MinKnow software (version 21.11.7) was then used to operate the MinION Mk1C (ONT) and basecalling was performed using Guppy (v. 5.1.13).

The quality of the initial reads was assessed using Nanoplot V.1.41.0 [25]. Genome assembly and annotation were conducted using the web-based Galaxy platform [26]. All obtained Nanopore raw reads were assembled using the Flye (v.2.9) [27] assembler, with the options—nano-raw, —scaffold and three internal rounds of self-polishing. Assembled sequences <1.000 bp in size were removed from the dataset (i.e., a single contig of 645 bp). The final assembly was evaluated using Quast (v.5.2.0) [28] and gfastats (v.1.2.1) to obtain the overall assembly metrics. Complementary, the genome completeness was estimated with the Benchmarking Universal Single-Copy Orthologs (BUSCO) (v.5.3.2) [29] using the ortholog dataset set for fungi (OrthoDB v.10) [30]. Genomic rRNA genes were detected using Barrnap (v.0.9) [31] and tRNA genes were identified using ARAGORN (v.1.2.36) [32]. Genomic repetitive elements were predicted and soft-masked using Repeat-Modeler (v.2.0.3) [33] and RepeatMasker (v.4.1.2-p1) [34]. Coding gene predictions were performed with AUGUSTUS (v.3.4.0) [35], with the species = *Botrytis cinerea* selected for training. The coding genes detected in the assembly were functionally annotated using DIAMOND (v.2.0.15) [36] against the UniProtKB Swiss-Prot database (UniProt Consortium., 2017) + Blast2Go (v.1.2.14) [37,38]; the EggNOG Mapper [39] and InterProScan [40,41] with all applications and default settings selected. The obtained annotation results were uploaded and compiled with the OmicsBox software (v.2.0), the Interpro protein domains, families and sites were obtained, the Gene Ontology (GOs) terms were merged, and the GOSlim tool and the enzyme coding mapping tools were applied. In parallel, the predicted protein-coding genes were mapped to the Kyoto Encyclopedia of Genes and Genomes (KEGG) using KofamKOALA [42] and reconstructed with the KEGG Mapper Reconstruct-

tion web server (https://www.genome.jp/kegg/tool/map_pathway.html, last accessed on 4 April 2023).

Analysis of putative secreted protein was conducted using SignalP (v.6.0) [43]. The obtained predicted proteins with signal peptides were then further evaluated to recognize putative membrane proteins (secretome) using DeepTMHMM (v.1.0.13) [44]. In parallel, EffectorP (v.3.0) was also applied to identify predicted fungal effectors [45]. Moreover, DIAMOND (v.2.0.15) [36] was used to compare the predicted proteins with the pathogen–host interaction database (PHI-database v.4.10) [46]. In parallel, carbohydrate-active enzymes (CAZymes/“CAZome”) were identified using the dbcan2 web-server [47]. Lastly, biosynthetic gene clusters (BGCs) were screened using the fungal version of antiSMASH web-server (v.6.0) [48], with the options: detection strictness set to strict and all extra features selected.

3. Results and Discussion

3.1. *Monilinia Fructicola* Isolation and Identification

During the field campaigns, flower necrosis was the most commonly observed symptom, appearing as an exudation that remained attached to the plant, although branches were also severely affected.

Pure cultures of *M. fructicola* were obtained from four isolates (6774, 779B, 754B and 160E) collected from branches of orchards B and F (Figure 1a, Table 2). The identification was confirmed by conventional PCR. In detail, Basic Local Alignment Search Tool (BLAST) searches of the ITS sequence in GenBank showed the highest similarity (99%) to the sequences of *M. fructicola* isolates from the Netherlands (MH864497.1) and Serbia (MT804333.1). The phylogenetic analysis performed with the reference sequences also confirmed this identification (Figure 2). The method developed by Van Brouwershaven et al. [17] was applied to the isolates and confirmed the previous results.

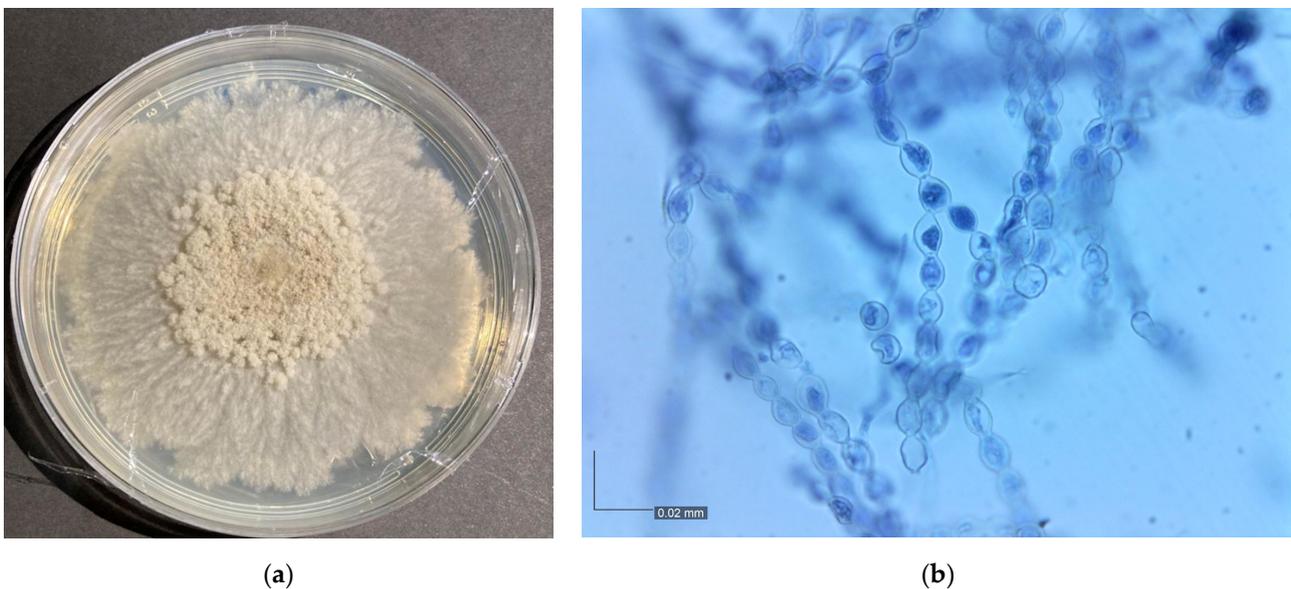

Figure 1. (a) Isolated colony of *Monilinia fructicola* isolate 160E growing on PDA media after seven days of inoculation; (b) Microscopic morphology of *Monilinia fructicola* isolate 160E, composed of ellipsoid conidia attached in branched chains, stained with lactophenol cotton blue ($\times 40$ microscope, bars represent 0.020 mm).

Table 2. *Monilinia fructicola* detection according to plant material and detection method (X).

| Region | Orchard | Sampled Tree | Plant Material | Morphology | PCR (ITS) | RT-PCR |
|--------|---------|--------------|----------------|------------|-----------|--------|
| North | A | 6 | branch | | | x |
| | | 1 | flowers | | | x |
| | | | branch | | | x |
| | B | 2 | branch | x | x | x |
| | | 4 | branch | | | x |
| | | 5 | branch | x | x | x |
| | | 7 | branch | | | x |
| | | 8 | branch | x | x | x |
| | E | 1 | branch | | | x |
| | F | 2 | branch | x | x | x |

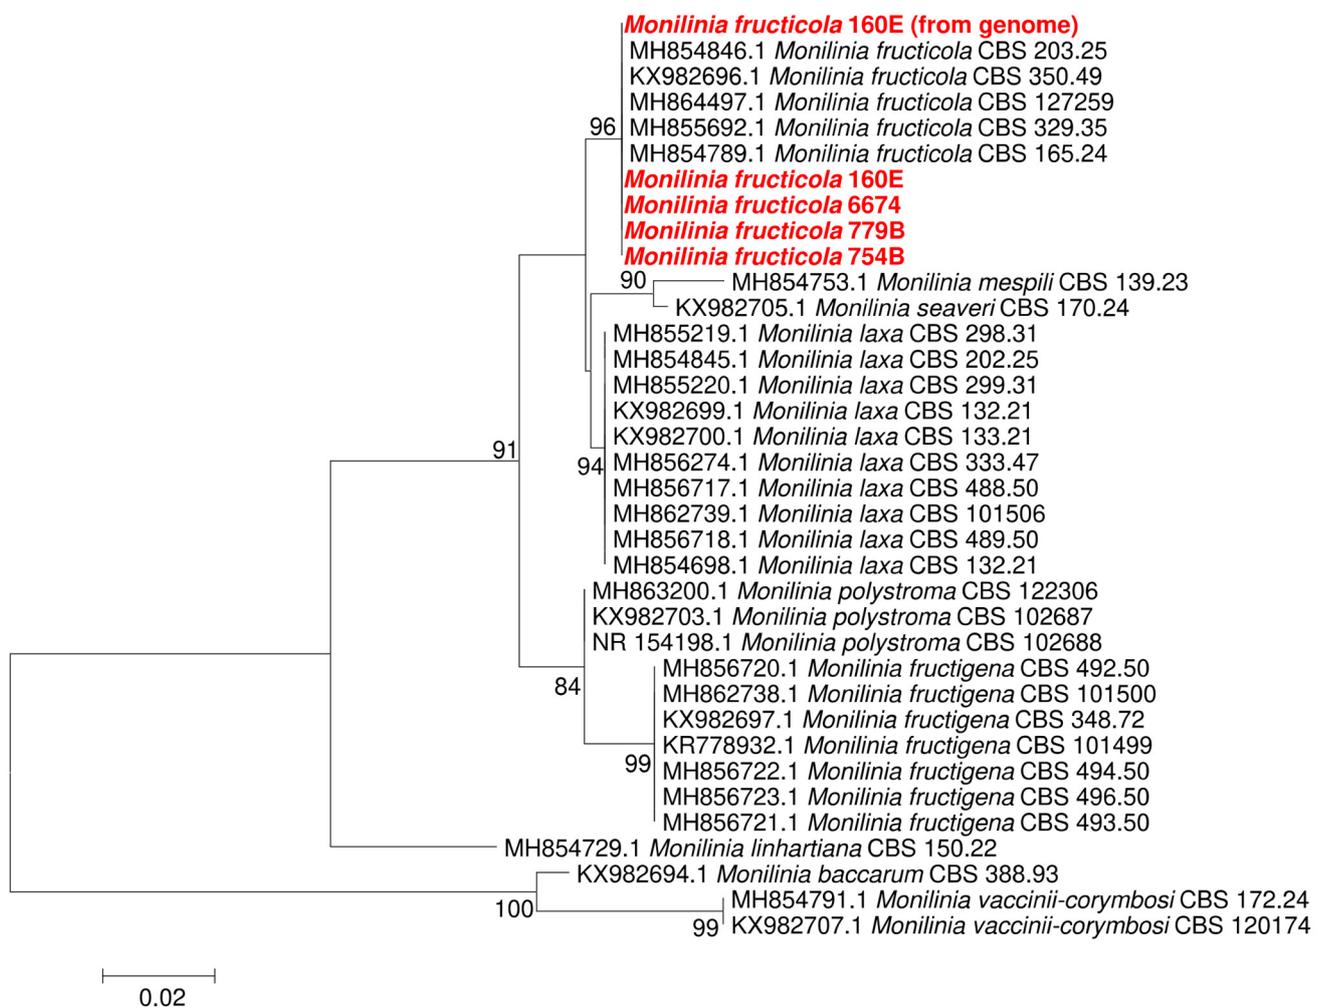

Figure 2. Maximum likelihood tree obtained using the partial ITS sequence alignment obtained with closely related *Monilinia* species reference sequences. The sequences obtained in this study are presented in red and bold. The scale bar indicates the expected number of substitutions per site and the bootstrap support values (>75% based on 1000 replicates) are also shown.

M. fructicola isolates were grey, the sporulation produced concentric rings, and the macroconidia were hyaline and ovoid [49]. The characteristic morphological structures

described in the literature were observed, namely ellipsoid and lemon-shaped conidia connected by chains (Figure 1b).

Species of *Monilinia* are very difficult to distinguish based on morphological characteristics and growth parameters alone, therefore molecular characteristics play an important role in accurate identification [10,50]. The method developed by Van Brouwershaven et al. [17] was additionally applied to total DNA plant extracts (Table 1) and allowed the additional detection of *M. fructicola* in 9 samples from orchards A, B, E and F (Table 2).

3.2. Pathogenicity Tests

The principles of Koch's postulates were applied to confirm that the typical brown rot symptoms observed in the field were caused by isolate 160E identified as *M. fructicola*. The control treatment showed no symptoms of *M. fructicola* infection (Figure 3a–c), whereas fruits inoculated with the isolate 160E showed initial symptoms after two days and the typical brown rot symptoms appeared after seven days (Figure 3d–f). The pathogen was re-isolated from the inoculated fruits and cultured on PDA media and was morphologically and molecularly confirmed as *M. fructicola*.

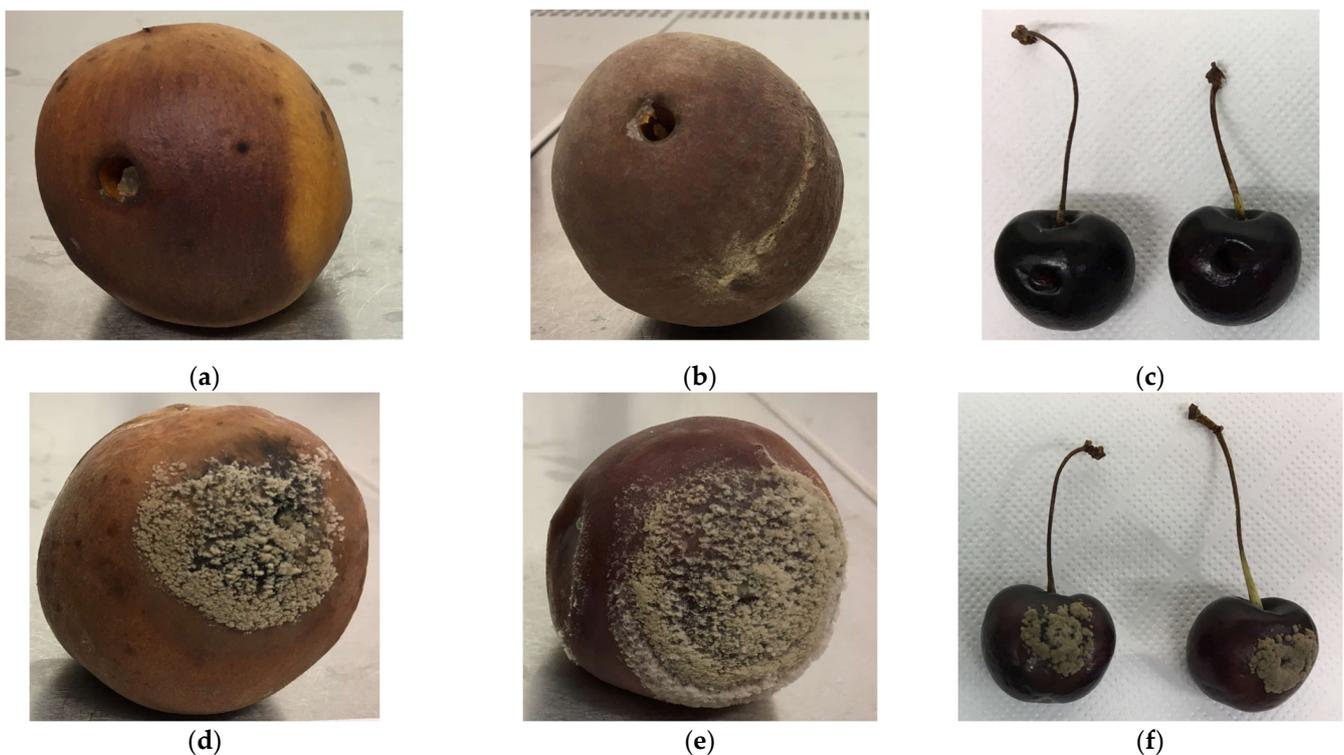

Figure 3. Koch's postulates were applied to nectarine, peach, and sweet cherry, (a–c) inoculated with PDA media, and (d–f) inoculated with *Monilinia fructicola* isolate 160E. Photos taken seven days after inoculation.

3.3. Genome Assembly

The whole genome of *M. fructicola* isolate 160E was sequenced using the Oxford Nanopore Technology (ONT) platform, consisting of 44,541,355 bp, assembled into 22 contigs/scaffolds (109× average coverage with circularization achieved for two contigs/scaffolds (Table 3) with a GC content of 40.54%). Manual BLAST analysis against the National Center for Biotechnology Information (NCBI) genome database indicates that contig_31 corresponds to the *M. fructicola* mitochondrial genome, while contig_35 corresponds to *M. fructicola* genomic material (possibly indicating the presence of extrachromosomal DNA (ecDNA), pending further studies). Overall, when comparing these results with the currently avail-

able literature, this assembly is consistent with the genomes of the species studied by De Miccolis Angelini et al. [51] (with 20 contigs).

Table 3. Overall Flye assembly info obtained of *Monilinia fructicola* isolate 160E.

| #Seq_Name | Length | Cov. | Circ. | Repeat |

The Benchmarking Universal Single-Copy Orthologs (BUSCO) completeness was estimated to be 91% for fungi ($n = 758$), with 690 complete BUSCOs, 689 complete and single-copy BUSCOs, one complete and duplicated BUSCO, 38 fragmented BUSCOs and 30 missing BUSCOs (Figure 4). As such, these results are consistent with the values found for *M. fructicola* completeness, which typically range from 88% to 98.7% [51,52].

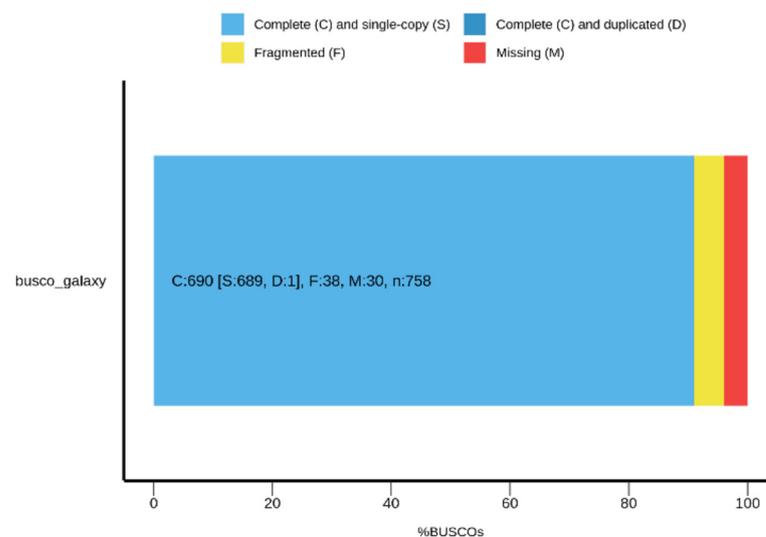

Figure 4. Genome completeness as evaluated with BUSCO.

ONT is one of the most rapidly developing Next Generation Sequencing (NGS) technologies to date, with its own set of advantages and disadvantages. The Achilles heel of this technology is its sequencing error rate, which is still higher than other NGS technologies.

However, ONT has made significant progress in addressing this issue, resulting in the latest quality score being set at Q20+. Several approaches can be taken to overcome the error barrier. Firstly, increasing coverage, and in this work, we have achieved a coverage of 109X. Secondly, native sequencing to eliminate polymerase amplification errors, which was also performed in this study (Table 4). Finally, the assembly of long reads can minimize assembly errors. In addition to these advances, fungal identification was carried out using several techniques: RT-PCR, ITS gene Sanger sequencing and genome sequencing. All were successful in identifying *M. fruticola*. Furthermore, the comparison of the ITS sequences obtained by Sanger sequencing and ONT-based genome sequencing showed 100% similarity (Figure 2).

Table 4. Overall genome assembly metrics of *Monilinia fruticola* isolate 160E.

| Info | Value |
|-------------------------|-----------------|
| Total scaffold length | 44,541,355 |

| Initial number of reads | 1,003,591 reads |
| mean read_length | 4742.1 |
| mean qual | 12.5 |
| Reads >Q8 | 100% |
| Reads >Q10 | 90.0% |
| #N's per 100 kbp | 0 |
| #N's | 0 |

3.4. Genome Annotation and Functional Characterization

In total, AUGUSTUS predicted the presence of 9603 genes, with 121 tRNAs and tmRNAs; and 12 rRNAs (4 18S rRNAs, 4 28S rRNAs and 4 5.8S rRNAs). This result highlights a somewhat slightly lower number of predicted genes when compared for instance with the results obtained by De Miccolis Angelini et al. [51] (13,749) and Vilanova et al. [52] (10,086). On the other hand, from the initial 44,541,355 bp, RepeatMasker detected and masked 5,621,921 bp (12.62% of the assembly) (Table S1), a value higher than the one observed by De Miccolis Angelini et al. [51] (4.13% of the full genome size). Overall, the vast majority of these had a classification of unclassified (6.29%), followed by retroelements (1.389%) and DNA transposons (0.58%) (Table S1).

From the whole genome annotation (Table S2), the functional analysis considering GOs, revealed that the top five most representative domains for (1) biological processes were: cellular process, metabolic process, organic substance metabolic process, primary metabolic process and nitrogen compound metabolic process (Table S3); (2) cellular components were: cellular anatomical entity, organelle, intracellular anatomical structure, intracellular organelle and membrane-bounded organelle (Table S4); and (3) molecular function were: catalytic activity, binding, hydrolase activity, transferase activity and organic cyclic compound binding (Table S5) (as similarly verified by De Miccolis Angelini et al. [51]). On the other hand, of the 9603 genes, InterProScan predicted information about proteins' function from 9181 with IPS, revealing that the top five most representative (1) families were: (IPR027417) P-loop containing nucleoside triphosphate hydrolase, (IPR036291) NAD(P)-binding domain superfamily, (IPR036259) MFS transporter superfamily, (IPR029058) Alpha/Beta hydrolase fold and (IPR011701) Major facilitator superfamily (Table S6); (2) domains were: ((IPR020846) major facilitator superfamily domain, (IPR000719) Protein kinase domain, (IPR001138) Zn(2)-C6 fungal-type DNA-binding domain, (IPR003593) AAA+ ATPase domain and (IPR007219) Transcription factor domain, fungi (Table S7); and (3) sites were: (IPR008271) Serine/threonine-protein kinase, active site, (IPR005829) Sugar transporter, conserved site, (IPR017441) Protein kinase, ATP binding site, (IPR019775) WD40 repeat, conserved site and (IPR017972) Cytochrome P450, conserved site (Table S8). Overall, these results point to the presence of an important representation of processes related to gene,

cellular signalling and transcription regulation, as well as, cellular processes and cell cycle control, as evidenced for instance by the high number of IPR005829, IPR017441 and IPR019775 detections. On the other hand, also highly relevant are the abundances of major facilitator transporters (MFS), since they are particularly relevant to mediate resistance to toxic compounds and can be viewed as genomic evidence of tolerance (e.g., [53]).

The Omicsbox enzyme coding map tool detected seven main enzyme classes (Figure 5). Of these, the overall most represented were hydrolases, transferases and oxidoreductases (Table S9–S16; Figure MS1). The high abundance of hydrolases and oxidoreductases is relevant considering that they are required for lignin and cellulose degradation [54]. In parallel, the results obtained with the EggNOG mapper revealed that the most relevant Clusters of Orthologous Genes (COGs) category groups were: S (unknown function) (n = 2073), O (Post-translational modification, protein turnover, chaperone functions) (n = 486), G (Carbohydrate metabolism and transport) (n = 471), E (Amino Acid metabolism and transport) (n = 377) and U (Intracellular trafficking and secretion) (n = 372) among others (Table S17).

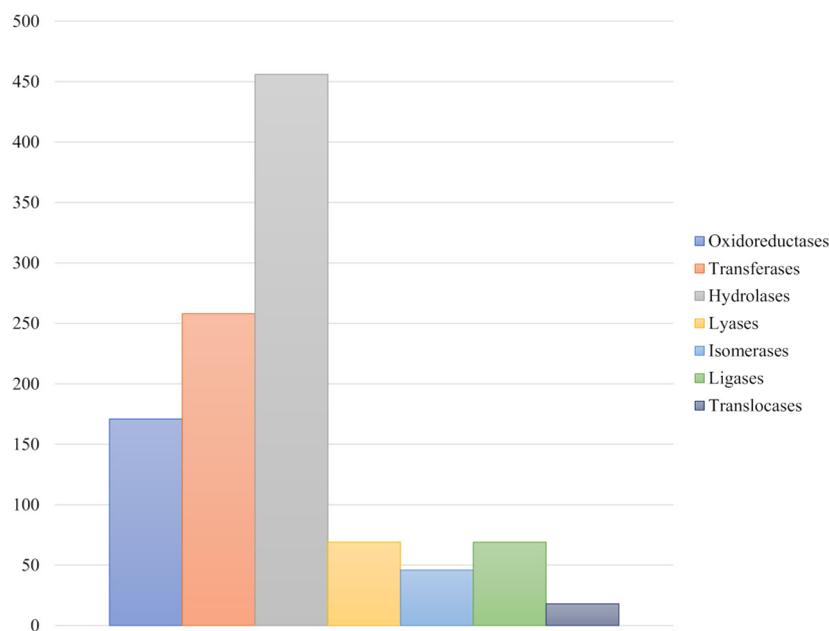

Figure 5. Abundance of the main enzyme classes detected using the Omicsbox enzyme coding map tool.

SignalP detected 754 predicted proteins containing signal peptides, a similar number found in other genomes of this species [51,52,55]. When considering the overall results obtained, DeepTMHMM predicted 487 Globular (Globs), 152 Signal Peptides (SPs), 103 alpha-helix Transmembrane (TMs) and 12 SP+TMs (Table S18). From these, in terms of region types, 313 were classified as TMhelix (transmembrane helices), 164 were classified as signal (Signal peptide), 285 were labelled as inside (Cytoplasmic) and 782 were labelled as outside (Extracellular). In addition, EffectorP categorizes effectors into apoplasmic (apoplast or fungal cell wall) [56,57] and cytoplasmic effectors (transported into the plant cell, sometimes to plant compartments). Overall, EffectorP detected 474 non-effectors, 181 apoplasmic effectors, 75 cytoplasmic effectors, 18 cytoplasmic/apoplasmic effectors and 6 apoplasmic/cytoplasmic effectors in the SignalP dataset (Table S19). Considering that proteins with a signal peptide, no transmembrane structure and effector candidates can be considered secreted (secretome), their number accounted for a total of 152 proteins, from these being 103 non-effectors, 36 apoplasmic effectors, 9 cytoplasmic effectors, 3 cytoplasmic/apoplasmic effectors and 1 apoplasmic/cytoplasmic effector (Table S20). On the other hand, the results obtained through the comparison with the pathogen–host

interaction database revealed that 228 proteins had a significant match, with the most prevalent result being Endo-1 4-beta xylanase [GH10 family *Magnaporthe oryzae* reduced virulence] (6 counts) and also highlighting the phytosanitary problems of this species.

The dbCAN2 tool identified 692 carbohydrate-active enzymes (CAZome) (Table S20). Cazymes are particularly important in plant pathogenic fungi since they allow tissue breakdown, nutrient acquisition, establish infection and/or interfere with the host plant's defences [52,55,58]. In general, the frequency of the enzyme families detected in this study was largely dominated by GH (glycoside hydrolases GH28, GH3 and GH18), AA (auxiliary activities AA3_2 and AA8_e0) and GT (glycosyltransferases GT2) (Table S21). Very few carbohydrate esterases (CE) and PL (polysaccharide lyases) were detected in the CAZome. These results are of extreme relevance considering that, for instance, the high number of GH28 is known to be expanded in necrotrophs [58], contributing to plant disease.

The fungal antiSMASH tool predicted ten putative BGCs, namely six T1PKS clusters, two NRPs clusters and two terpenes, being in accordance with what is found in other genomes of this species [52]. All of the predicted BGCs had somewhat low similarities with the MiBiG database [59,60] except for a T1PKS cluster, with 100% similarity with 1,3,6,8-tetrahydroxynaphthalene, a critical precursor to the DHN (1,8-Dihydroxynaphthalene) melanin biosynthesis. While commonly, *M. fructicola* contains two orthologous clusters contributing to the synthesis of melanin, in this study only one could be detected, a result that can affect virulence. Moreover, the detection of genes related to the synthesis of botcinic acid could also be detected, a phytotoxic polyketide, is also relevant, even with a lower similarity than expected (33%) (e.g., [55]). Nonetheless, through the BGC analysis, it is also possible to verify that the species can synthesize other additional yet putative unknown compounds, which will require further studies in the future.

4. Conclusions

Over the last two years, peach orchards in the Cova da Beira region have experienced a progressive decline in plants, with symptoms characterized by flower abortion with the production of exudates, cankers on the branches and, in some cases, death. This situation has resulted in significant losses for the growers of the orchards affected. In this scenario, procedures were established to identify the causal agent responsible for the observed decline, and *M. fructicola* was detected for the first time in Portugal in *P. persica*.

This regulated organism was detected and confirmed in nine of the forty-six samples analyzed (flowers and branches), corresponding to four of the thirteen orchards sampled, all located in the northern region of Cova da Beira. These results suggest that the distribution of the disease is still limited in the region studied, being restricted to geographically close orchards, all located north of Serra da Gardunha. However, it was possible to observe the spread of the symptoms associated with the disease within the orchards over the two years of the study, as well as an increase in the severity of these symptoms on infected plants over time.

Stone fruits such as sweet cherry, peach and nectarine are economically important for the Portuguese fruit sector. The presence of *M. fructicola* described in this work will certainly affect the national production of peach and nectarine in the coming years since Cova da Beira is the main production area. However, this evidence will contribute decisively to the awareness of phytosanitary authorities and producers of the presence of a regulated and harmful organism, allowing the implementation of specific phytosanitary management measures aimed at limiting the spread of the disease within the orchard and between orchards, thus reducing its impact on the productivity of the sector.
