Abstract: Forest change and climatic variability are two major drivers for influencing change in watershed hydrology in forest-dominated watersheds. Quantifying their relative contributions is important to fully understand their individual effects. This review paper summarizes the progress on quantifying the relative contributions of forest or land cover change and climatic variability to hydrology in large watersheds using available case studies. It compared pros and cons of various research methods, identified research challenges and proposed future research priorities. Our synthesis shows that the relative hydrological effects of forest changes and climatic variability are largely dependent on their own change magnitudes and watershed characteristics. In some severely disturbed watersheds, impacts of forest changes or land use changes can be as important as those from climatic variability. This paper provides a brief review on eight selected research methods for this type of research. Because each method or technique has its own strengths and weaknesses, combining two or more methods is a more robust approach than using any single method alone. Future research priorities include conducting more case studies, refining research methods, and considering mechanism-based research using landscape ecology and geochemistry approaches.

Keywords: forest change; climate variability; large watershed hydrology; relative contribution; research methods

1. Introduction

Studies on the relationship between forests and water in forested watersheds have been conducted over the last century. Researchers have provided reviews at different times [1–6]. The general conclusions are that forest removal increases annual mean flow, peak flow and base flow when soils are not significantly disturbed. This relationship can be reversed if forest change is associated with soil compaction and decreased infiltration [7]. However, the majority of these conclusions is from the studies conducted in small watersheds, usually less than 100 km², and cannot simply be extrapolated to large watersheds (more than 1000 km²). This suggests that more studies on the relationship between forest change and water in large watersheds must be conducted separately. In large watersheds, research targeting the relationship between forest changes and water is limited. There are many reasons contributing to fewer large watershed studies. The first and perhaps the most important reason is that paired watershed approach is not suitable for large watersheds because of the difficulty of locating reference watersheds with similar climate, vegetation and topography. The second reason is that large watersheds have different land uses and their complex interactions. Additionally, large watersheds very rarely coincide with the long-term records of hydrology, land use, and climate that exist for smaller research watersheds. However, with the expanding scope of land use planning and environmental protection, resource managers and planners require appropriate information at large watersheds or landscapes to support management decisions. Therefore, large watershed studies are urgently needed.

It has been widely accepted that climate variability and land cover or land use changes are two critical drivers for influencing watershed hydrological changes. Because of this, it is important to separate their relative contributions to hydrological change so that their individual effects can be quantified. In small watersheds, a paired watersheds approach is usually used to remove the effect of climate variability so that the effects of forest or land cover changes can be quantitatively assessed. However, this experimental paired watersheds approach is generally not feasible for large watersheds. Thus, alternative methods must be used for studying this subject in large watersheds. In the past 20–30 years, researchers have developed and applied diverse techniques for this research subject. These techniques can be broadly classified into statistical and modeling (process-based watershed modeling) categories. The objectives of this review are: (1) to describe various existing research methods and compare their pros and cons; (2) to briefly summarize the progress on quantifying the relative contributions of forest or land cover change and climatic variability to hydrology in large watersheds using available case studies; and (3) to identify research challenges and propose future research priorities.

2. Research Methods

2.1. Hydrological Modeling

Hydrological models are frequently used in the large watershed hydrological research. Hydrological models can be divided into lumped, semi-distributed and fully-distributed models. Lumped hydrological models study the watershed as a whole, and do not consider the detailed, spatial representations of watershed elements and processes. Unlike lumped or semi-distributed models, distributed models can well represent a watershed by assigning input data and physical characteristics to grids or elements. Physically based distributed models are able to provide distributed approximations or predictions of hydrological variables across watersheds, and thus have a better representation of reality. However, a fully-distributed model requires a large dataset with data on various processes, components and their interactions. For a large-scale watershed research, a semi-distributed model is commonly used because of a general absence of detailed data at large scales.

The one-factor-at-a-time approach (OFAT) commonly used in sensitivity analysis [8–10] is also used in association with hydrological models to distinguish the impact of climate factors and land cover change on watershed hydrology [11,12]. In a hypothetical example, the impacts of climatic variability and land use change on runoff are assessed with the available data in the period of 1960 to 2000. First, we keep the land cover in 1960 unchanged over the simulation period while climate change is allowed from 1960 to 2000. Then we simulate the runoff change (ΔQ_C), which can be treated as the impact of climatic variability on hydrology. Second, keep the climate of 1960 unchanged while land cover is changed, then calculate the runoff change (ΔQ_L) as the impact of land cover change. Finally, we assume the changes of both climate and land cover, then calculate the runoff change (ΔQ_{L+C}). In this way, the relative contributions of forest and land cover changes and climatic variability to hydrology can be computed.

Various distributed hydrological models have been successfully used to quantitatively study the effects of climate change and forest change/land cover change on hydrology, for examples, SWAT [13,14], DHSVM [15–17], MIKE-SHE [18], *etc.* In spite of increased applications, hydrological models are still based on our current theories that are deeply rooted in the physics of small-scale processes. This gives rise to difficulties in representing nonlinear hydrological processes and their interactions at all scales across heterogeneous landscapes. In addition, calibrating and testing a model may not always assure its validity, since there are some inherent drawbacks in the approaches of parameter calibration and validation. We often over-parameterize our models to meet high accuracy levels, ignoring the equifinality problem that different parameter sets for a model might yield the same result during calibration, but distinctly different predictions when conditions are altered [19,20].

2.2. Trend Analysis

Trend analysis is a commonly used method to qualitatively assess hydrologic responses [21–24]. The trend analysis uses historic data to fit a curve, which reflects a trend of the interested hydrological variable and can then be used to predict any future values if the trend is statistically significant.

$$b = \text{Median} \left(\frac{x_j - x_1}{j - 1} \right) \forall \langle j \rangle \quad (1)$$

$$B = 100 * \frac{Tb}{E(x)} (\%) \quad (2)$$

$$r = 1 - \frac{\sum_{i=1}^n di^2}{n^3 - n} \quad (3)$$

where the Equation (1) is used to calculate the slope of a time series data; the Equation (2) is used to estimate change percentages of the sample mean $E(x)$; and the Equation (3) is for correlation coefficient at a significant level.

When the trend analysis is applied to detect the effects of forest change on hydrology, information on climate change and land use change is needed. If there is no a significant trend in climate variable (e.g., precipitation), the significant trend in hydrological variable is then judged to be caused by forest change or land cover change [24,25]. Clearly, this method is simple and qualitative, but may not be reliable, as the interactions between forest change and climatic variability are not considered. Wei and Zhang detected the offsetting effects of forest change and climatic variability on annual streamflow, which caused an insignificant trend on annual mean flow even though the forest effects on hydrology were statistically significant [26].

2.3. Double Mass Curves

Double Mass Curve (DMC) is a simple and intuitive method, widely used in long-term trend analysis of hydrometeorological elements. DMC draws a curve between two cumulative hydro-meteorological variables to test the consistency of two variables or analyze the trend change and its strength [27–30]. DMC method can be also used to separate the relative influences of forest change and climatic effects to hydrology [31]. For example, a modified DMC (MDMC) between cumulative annual streamflow and cumulative effective precipitation (the difference between total precipitation and evapotranspiration) is constructed for a large forested watershed (Figure 1). In this way, climatic effect on annual streamflow can be eliminated. In the period of no forest disturbance, the curve should produce a straight line, a baseline that describes the linear relation between annual streamflow and annual effective precipitation, and a break in this curve (e.g., year 1986 in Figure 2) would suggest the change of annual streamflow caused by forest disturbance. In other words, a step change or regime shift occurs in the slope of MDMC and the slope before the break is different from that afterwards. However, this visually detected breakpoint needs confirmation of its statistical significance by a non-parametric test or application of ARIMA model [32,33]. The difference between actual observations and the predict line after the change point can be calculated, and is regarded as the cumulative impact of forest changes.

2.4. Quasi-Paired Watershed Method

Paired watershed method compares two adjacent basins with similarity in size, morphology, geology, climate and vegetation including one as control and the other as treatment. The method is widely used in studying forest-water relationship in small (<100 km²) watersheds. For large watersheds, the concept of “quasi-paired watersheds” was proposed [34]. The quasi-paired watersheds method chooses two or more basin, with relative similarity in size, morphology, geology, climate and vegetation, but different

forest disturbance levels. In this method, the watershed experienced the least forest disturbance is treated as “control”. Double mass curves of runoff coefficients (annual runoff/precipitation) obtained by plotting accumulated coefficients of the “treated” (Ct) against those of the “control” watershed (Cc), are used to detect the effect of forest disturbance on annual mean flow. If the “treated” watershed undergoes insignificant disturbance, a straight line would be expected. Otherwise, a break in the observed line indicates the emerging effect of forest disturbances on a hydrological variable (e.g., annual mean flow), and the difference between the expected and observed lines can be attributed to the difference in forest disturbances between “control” and “treated” watersheds. Statistical significance of the breakpoint found in the DMC slope can be tested using ARIMA intervention analysis [35,36].

Figure 1. A hypothetical example of application of the MDMC (modified double mass curve) between cumulative annual runoff (Q_a) and cumulative annual effective precipitation (P_{ae}) for assessing the effects of forest change on annual mean flow.

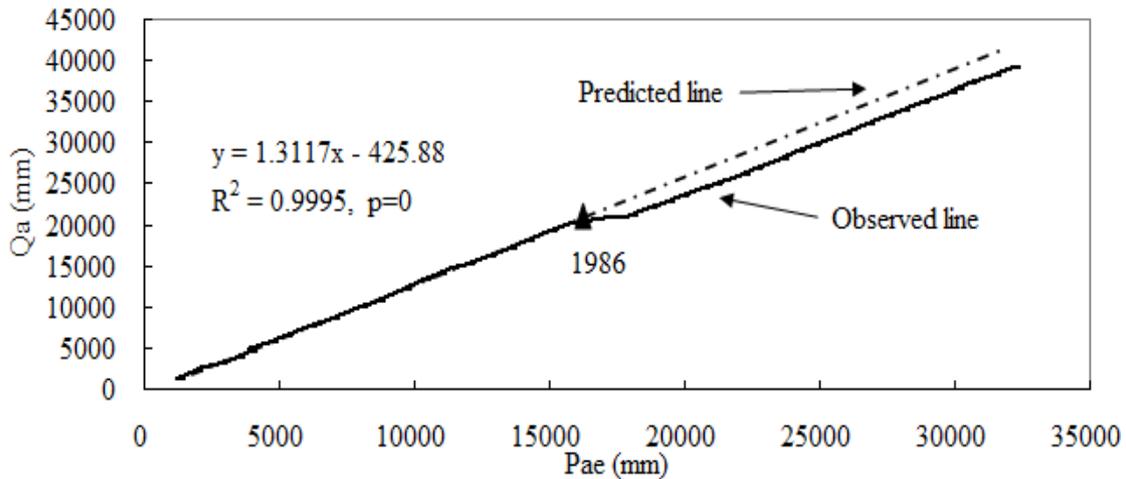

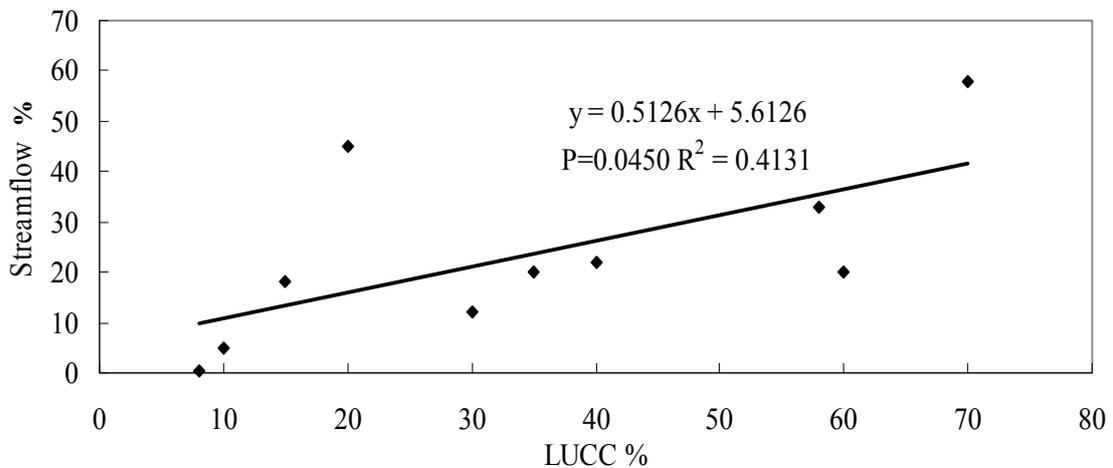

Figure 2. Relationship between forest or land cover changes (LUCC) and their relative contributions to streamflow.

The method is an alternative approach to the paired watersheds method where there are two similar watersheds with contrasted forest disturbance levels or land use changes. If long-term data are available, such a method can provide reliable results as what the paired experimental watersheds do. The challenge of this method is that it requires the “treated” watershed must have two significant long periods with and without severe forest disturbance. In addition, both watersheds should have relative similarity in climate, soil and vegetation. This could impose some difficulties in large watersheds where great spatial heterogeneities and complexities always exist.

2.5. Sensitivity-Based Approach

Sensitivity-based approach is similar to elasticity method [37], and is used to calculate the effect of climate variability on streamflow. Perturbations in both precipitation and PET can lead to changes of water balance. It can be assumed that a change in mean annual runoff can be determined using the following expression [31,38]:

$$\Delta Q_{\text{clim}} = \beta \Delta P + \gamma \Delta \text{PET} \quad (4)$$

where ΔQ_{clim} , ΔP , and ΔPET are changes in streamflow, precipitation, and potential evapotranspiration, respectively, and β and γ are the sensitivity coefficients of streamflow to precipitation and potential evapotranspiration, expressed as:

$$\beta = \frac{(1 + 2x + 3wx^2)^2}{(1 + w + wx^2)^2} \quad (5)$$

$$\gamma = \frac{(1 + 2wx)}{(1 + x + wx^2)^2} \quad (6)$$

where x is the mean annual index of dryness (equal to PET/P); and the values of vegetation factor w for forest, grassland and shrub land are 2, 0.5 and 1, respectively [39].

This method is suitable for the analysis of a single basin, and for quantitative calculation of the impact of climate variables on runoff. Once the effects of climatic variability on flow are estimated, the effects of forest disturbance or land use changes can be deducted from total streamflow variations. The method has been successfully used for several case studies [37–39]. There may be two challenges in this method. First, it is not easy to determine w values for specific forest vegetation types. Where there are always different types of forests in a large watershed, how to select a specific w value remains challenging. Second, the effect of forest disturbance or land use changes on hydrology is indirectly estimated from total hydrological variations and the effects of climatic variability. Thus, its reliability is dependent on the accuracy of the other two terms.

2.6. Simple Water Balance

The water balance methods provide a framework to determine changes in the water balance components [40]. Simple water balance model can be used to determine the influence of climate and vegetation on streamflow at a watershed scale.

$$P = ET + Q + \Delta S \quad (7)$$

where P is precipitation, ET is actual evapotranspiration, Q is streamflow and S is change in catchment water storage. When averaged over a long period, deep percolation (recharge) and change in soil moisture storage is often only 5% to 10% of the annual water balance, and therefore the change in catchment water storage (ΔS) can be neglected [41,42].

Precipitation and actual evapotranspiration constitute the most important variables to influence runoff change at the watershed scale. Precipitation, which varies both in temporal trend and spatial distribution, is regarded as independent of vegetation types [39], which mainly reflects changes of climate. However, actual evapotranspiration is a complex process. There are various ways to estimate watershed-scale evapotranspiration. For example, following the Budyko's hypothesis, the simple two-parameter model for estimating the actual evapotranspiration was developed [43,44]. The model is consistent with the previous theoretical work and shows good agreement with more than 250 catchment-scale measurements from around the world [39,45,46].

$$\frac{ET}{P} = \frac{1 + w \left(\frac{ET}{P} \right)}{1 + w \left(\frac{ET}{P} \right) + \left(\frac{ET_0}{P} \right)^{-1}} \quad (8)$$

where ET is the actual evapotranspiration, ET_0 is reference evapotranspiration as substitute of potential evapotranspiration calculated by the P-M method. The w is the plant-available water coefficient estimated in the same way as in the sensitivity-based approach [39].

The following steps were used to describe how a simple water balance method is implemented to estimate the effects of forest change on hydrology [40]. They are described as follows. First, according to Equation (8), calculate the actual evapotranspiration using the original data including precipitation, air temperature, relative humidity, wind speeds and sunshine hours after calculating ET_0 by the P-M method. Second, estimate annual runoff using the Equation (10). In this step, the change of annual runoff is influenced by both climate variability and vegetation changes, and thus, the calculated annual runoff can be defined as Q_{v+c} ; Third, removing the decreasing or increasing trend of precipitation, air temperature, relative humidity, wind speeds and sunshine hours in data series to make them as stationary time series [47], recalculate the ET_0 using the detrended climate variables and estimate annual runoff according to the Equations (10) and (11). In this step, the change of annual runoff mainly reflects the influences of vegetation changes, and thus, the recalculated annual runoff can be defined as Q_v . Finally, calculate the difference between Q_{v+c} and Q_v so the change of annual runoff caused by the climate variability can then be estimated [40].

A simple water balance method provides a new way to distinguish the impact of climatic variables and vegetation factors on hydrological change. However, the choice of w values and the difficulty associated with removal of the decreasing or increasing trends in climate data may introduce some errors in this method.

2.7. Time Trend Method

In the time trend method, a relationship is established between discharge and climatic variables before the basin's vegetation perturbation occurs and is then used to predict the discharge response of post-perturbation assuming undisturbed basin conditions. The typical time trend approach is to divide the whole study period into the calibration section and prediction section. The model accuracy depends on the length of the calibration or pre-perturbation periods [48].

During the calibration section:

$$Q_1 = aP_1 + b \quad (9)$$

During the forecast section:

$$Q_2 = aP_2 + b \quad (10)$$

$$\Delta Q_{veg} = \overline{Q_2} - \overline{Q_1} \quad (11)$$

where P is precipitation, Q is runoff, Q' is the predicted streamflow for the treated catchment (from using Equation (9) developed during the calibration period), ΔQ_{veg} represents the change in mean annual streamflow because of vegetation change, subscripts 1 and 2 represent the calibration period and the prediction period, and b is the fitted regression coefficient.

This method uses a simple regression to express the relationship between precipitation and runoff both before and after forest cover changes. The method only requires data of precipitation, runoff and other meteorological variables, and the requirement on the detailed forest cover change can be ignored to some extent. The method may accept discontinuous data. Depending on different hydrometeorological characteristics in a study basin, time trend method performance at yearly hydrological variables is better than on the variables at monthly or daily intervals. Guardiola-Claramonte *et al.* proposed to consider the impact of temperature on the relationship between precipitation and runoff [49].

2.8. Tomer-Schilling Framework

Tomer and Schilling developed an elegant, coupled water–energy balance framework that requires long-term time series of precipitation (P), streamflow (Q), and PET to assess if unused available energy and water were related to climate and/or to land management in agricultural catchments [25,50]. The conceptual framework that qualitatively discriminates whether the dominant drivers of observed changes are related to land cover change and/or climate. The framework relating changes in land cover change and/or climate to the observed changes in the excess amounts of water (P_{ex}) and excess amounts of energy (E_{ex}) as fractions is illustrated in Peña-Arancibia *et al.* [25].

The Tomer–Schilling framework assumes that land cover change will affect ET but not P or PET , acknowledging that effects of land cover change on P and PET can be considered indirect at this scale and of second order when compared to changes in ET in the woodland environment. Thus, land cover change will cause ecohydrological shifts towards increased P_{ex} and E_{ex} , or towards decreased P_{ex} and E_{ex} . Changes in climate are required to cause increased P_{ex} and decreased E_{ex} , due to the temporal increase in the P/PET ratio and vice versa [25].

$$\overline{P_{ex}} = \frac{(\overline{P} - \overline{ET})}{\overline{P}} \quad (12)$$

$$E_{ex} = \frac{(\overline{PET} - \overline{ET})}{\overline{PET}} \quad (13)$$

Tomer-Schilling framework is an effective and qualitative analysis tool of hydrological processes. The method can not only analyze long-term impacts of climate and forest cover on hydrology, but also explain the main factors of hydrological responses in different time periods. However, as all the qualitative methods, the impact of each variable of climate or vegetation cannot be quantitatively evaluated, and this brings difficulties to study the common law of hydrological responses under different topographies and different vegetation types.

3. Research Progress

Table 1 summarizes the progress on quantifying the relative contributions of climate variability and forest or land cover changes to hydrology in large watersheds. As shown in Table 1, more researchers have used statistical methods, while the others have applied the modeling approach. There are two reasons contributing to this difference. First, statistical methods normally analyze historic data for assessing the effects of forest change and climate variability, while models predict the possible effects of future scenarios on hydrology. With increasing availability of long-term data on hydrology, climate and land use change, it is not surprising that statistical methods gain more popularity due to their efficiency and provision of robust inferences. Hydrological models can be used to simulate the relative contributions of forest change and climate variability to hydrology, but they are limited due to the lack of various empirical relationships at large watersheds. Second, data on forest change or land over change are difficult to collect at large spatial scales across extended time periods. Without these data, models are difficult to calibrate. In comparison, some statistical methods such as trend analysis method, sensitivity-based approach and the elasticity method [51–55] can be used to quantify the effects of climatic variability first and then estimate the influence of forest or land cover change from the total variations. Those estimations can be done without long-term data on forest or land cover changes. However, in the watersheds where long-term and high quality data are not available for application of statistical approaches, models can be alternative approaches given that there are sufficient data for model calibration and validations.

Among the applied models (Table 1), SWAT, a semi-distributed model was widely used to evaluate the effects of climate and land use changes on streamflow [56,57]. It simulated streamflow responses to change in climate, land use, or both to distinguish the impact of climate variability from that of land use change on hydrology [35,58,59]. Other distributed hydrological models such as DTVGM model (Distributed Time-Variant Gain Model); VIC model (Variable Infiltration Capacity) and DHSVM model (Hydrology-Soil-Vegetation Model) were also applied to this research topic (Table 1). For example, lumped hydrological model (CHARM) and distributed model (TOP MODEL) were used to simulate the effect of climate variability and land cover change on hydrology in the upper reaches of the Yangtze River [58]. Three applied models show similar results, suggesting that their simulations were reliable.

There is a clear tendency that a combined approach of two or more complementary techniques (particularly the combination of statistical and modeling methods) is superior to application of a single technique alone. For example, both climate elasticity and hydrological modeling methods were applied to distinguish the effects of climate variability and human activities in Baiyangdian Basin [52]. Using the climate elasticity method, the results indicated that climate variations accounted for 40% of decrease in streamflow, while human activities accounted for 60%. Using the hydrological modeling method, the results showed that climate variations accounted for 38% of decrease in streamflow, while human activities accounted for 62%. Because two independent methods achieved relatively consistent results, the result was believed more reliable.

The general perception is that climate is dominant in influencing streamflow change [26,60,61]. However, Table 1 shows that the relative hydrological effects of climate variability and forest change or land use change are largely dependent on their own change magnitudes and watershed characteristics. In some severely disturbed watersheds, impacts of forest change or land cover change are as important as those from climate change. For example, large-scale land use changes and practices were found to be the most important factor responsible for the streamflow change in the northwest China's Loess Plateau (Table 1) [21,40]. Based on comparable studies listed in the Table 1, we detected that a significant linear relationship between forest or land cover changes and their contributions to streamflow changes (Figure 2). This significant linear relationship clearly demonstrated that the more severe change of forest or land cover, the greater in their relative contributions to hydrological changes. Another example showed that the forest disturbance (25%–30%) accounted for 45% of decrease in streamflow and is similar to that from climate change (55%) in Willow watershed located in the central interior of British Columbia, Canada [26].

Table 1. Summary of the studies on relative contributions of forest or land cover changes and climate variability to hydrology.

Method	Watershed (km ²)	Forest change or land use change (%) at a watershed	Relative contribution (%)		References
			Climate variability	Forest change/land use change	
Hydrological Modeling	The source regions of Yellow River (1.22 × 10 ⁵ km ²)	0.13%~34.03% area change in woodland and shrub/grassland	65%–95%	6%–16%	[56]
	Heihe River watershed (1506 km ²)	4.5% of the catchment area was changed mainly from shrubland and sparse	95.8%	9.6%	[57]
	Suomo Watershed (2536 km ²)	Forest area decreased by 17%, open woodland increased by 8%, grassland area increased by 10%	60%–80%	20%	[62]

Table 1. Cont.

Method	Watershed (km ²)	Forest change or land use change (%) at a watershed	Relative contribution (%)		References
			Climate variability	Forest change/land use change	
Hydrological Modeling	The upper Yangtze River watershed (13,721~1,005,501 km ²)	Human activities	55%–73.3%	28.5%–46.7%	[63]
	Chaobai River watershed (57,001 km ²)	Human activities	34%	64%	[64]
	Araguaia River watershed, Brazil (385,000 km ²)	55% Deforestation	33%	67%	[65]
Trend Analysis	Shiyang river watershed (389~1614 km ²)	Area change in Forest, crop and grassland	64.5%–87.9%	12.1%–35.5%	[66]
	Hun–Tai River watershed (1112~11,203 km ²)	Human activities	43%	57%	[67]
	Pyrenees Watershed, Spain (3.25 × 10 ⁴ km ²)	The increase of agricultural land	70%	30%	[68]
	Wuding River watershed (30,261 km ²)	43% (The soil conservation measures)	13%	87%	[45]
	Qingshui River watershed (436 km ²)	Cropland decreased by 72.1%, woodland increased by 963.60% and residential area increased by 576.07%	46.79%	53.21%	[69]
	Taoer River watershed (41,600 km ²)	Paddy field increased by 2%, upland increased by 15.10%, forest decreased by 10.60%	45%	55%	[61]
	ColumbiaRiver watershed, Canada (385,000 km ²)	Human activities	48%–55%	45%–52%	[70]
Double Mass Curves	The Willow River watershed, Canada (2,860 km ²)	19.7% Deforestation	55%	45%	[26]
	The Upper Zagunao River watershed (2528km ²)	15.5% Deforestation	42.5%	57.5%	[71]
Quasi-paired Watershed Method	Yulin, 8.28 km ² Xinlin, 28 km ²	Forest cover increased from 20% to 80%	/	8.61%	[30]
Sensitivity-Based Approach	Upper catchment of the Yellow River Watershed (222,551 km ²)	Human activities	50%	40%	[55]
	Baiyangdian Lake (3,465 km ²)	Construction of water conservation facilities	38%–40%	60%–62%	[52]
	The headwaters of the Yellow River Watershed (1.32 × 10 ⁵ km ²)	Water and soil conservation engineering	30%	70%	[72]

Table 1. Cont.

Method	Watershed (km ²)	Forest change or land use change (%) at a watershed	Relative contribution (%)		References
			Climate variability	Forest change/land use change	
Sensitivity-Based Approach	The Loess Plateau (1,279–9,289 km ²)	Water and soil conservation engineering	21%–57%	43%–79%	[21]
	Crawford River watershed, Darlot Creek watershed, Tinana Creek watershed (698–1,174 km ²)	Afforestation 13.4%–23.5%	21%–49%	61%–64%	[73]
Simple Water Balance	Yiluo River watershed (1.89 × 10 ⁵ km ²)	Water and soil conservation engineering	21.75%	78.26%	[40]
Time Trend Method	Seven paired catchments from Australia, New Zealand, and South Africa (0.18–3.44 km ²)	Clearing vegetation 32%–100% Afforestation 67%–83% Forest conversion 100%	10%–72%	28%–98%	[55]
	The upper reach of the Weihe River (1.35 × 10 ⁵ km ²)	Human activities	40%	60%	[64]
	Plata watershed, Paragury (3.2 × 10 ⁴ km ²)	Forest land converted to cropland	41%–53%	51%–59%	[74]
Tomer-Schilling Framework	Four candidate Midwest watersheds	Changes in agricultural land cover	Increase/decreased Pex and Eex	Increased Pex and decreased Eex	[50]

4. Future Research Challenges and Research Priorities

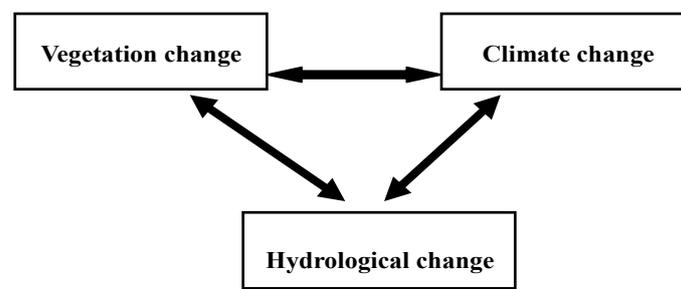

As mentioned previously, all methods summarized in this paper can be classified into two categories: statistics and simulation. The statistical methods normally provide robust inference about the relationship between hydrological responses and forest change or land cover changes. However, those methods treat a study basin as a black box, and rarely involve the mechanisms or processes. On the other hand, the simulation methods, especially fully-distributed models consider the hydrological processes and their interactions, but due to the lack of data and various empirical relationships in large watersheds, the model calibration and validation are often time consuming and inaccurate. Therefore, it is logical to believe that the combination of statistical methods and modeling can complement their strengths and overcome their shortcomings, and thus could be an improved research strategy.

Forest disturbance and climate change are considered to be the two main drivers interactively affecting the hydrological changes in large watersheds (Figure 3). Climate change can affect hydrology directly due to its influence on precipitation and temperature. Climate change can also affect hydrology in an indirect way. For example, more forest fires and pests can be induced by drought, and these forest disturbances in turn affect the hydrological processes. In an opposite way, vegetation can change evapotranspiration and thus streamflow. They can also affect hydrology indirectly. For example, vegetation types and distributions may affect the characteristics of air humidity, temperature, precipitation, and consequently hydrological cycle. As far as we know, the literature is extremely

limited on that topic, with some pioneering examples exploring the interactions among forest change, climate and hydrological responses [75,76].

In addition, current studies mainly focused on the changes in annual runoff, with less emphasis on peak and low flows. Assessing the relative contributions of forest or land cover changes and climatic variability to the change in peak and low flows is likely more challenging and may require separate methods such as geochemistry and landscape ecology in large watersheds. The isotope method in geochemistry could help analyze the sources (surface water, groundwater, glacier melt water, *etc.*) and flow pathways in the watersheds, while landscape ecology or geoscience allows us to examine the role of watershed configuration and topographic characteristics in the effects of the forest or land cover changes on hydrology [7,51,77–81]. However, such research is needed to support resource management decisions for protection of watershed functions and public safety in large watersheds or regions.

Figure 3. A conceptual framework showing interactions among climate change, forest change and hydrological responses.

Here, we propose the following future research priorities in this subject. First, more case studies are needed. Assessing the relative contributions of forest or land cover changes and climatic variability to hydrology is rather limited in large watersheds. Zhang and Wei compared two adjacent large watersheds located in the interior of British Columbia, and found the contrasted conclusions under the similar forest disturbance levels [35]. They further concluded that the effects of forest change on hydrology in large watersheds are likely watershed specific. This clearly demonstrates that more case studies are needed before generally conclusions can be derived. Second, a research priority should be given on improvement of research methods. Although quite a few research methods are currently available for studying the impacts of forest change and climate change on hydrology, there is no a commonly-accepted method. The lack of commonly-accepted methods may limit our ability to compare the results of different studies. Third, in large watershed studies, analytical results are largely based on data quality and spatial coverage. Large spatial variations in precipitation, temperature, solar radiation, humidity, wind speed, surface albedo, canopy characteristics, *etc.* in these large watersheds constraint our ability to derive robust conclusions. Future studies should be designed to specifically address uncertainties. Finally, more research should be on mechanisms and processes. It is difficult to study the mechanisms and processes in large watersheds, mainly due to lack of the suitable methodology and data for assessing the complicated interactions and cumulative behaviors across various spatial scales. However, such research is critical for explaining and verifying the findings obtained through statistical and modeling approaches.
