Abstract: Background: General pathophysiological mechanisms regarding associations between fluid administration and intra-abdominal hypertension (IAH) are evident, but specific effects of type, amount, and timing of fluids are less clear. Objectives: This review aims to summarize current knowledge on associations between fluid administration and intra-abdominal pressure (IAP) and fluid management in patients at risk of intra-abdominal hypertension and abdominal compartment syndrome (ACS). Methods: We performed a structured literature search from 1950 until May 2021 to identify evidence of associations between fluid management and intra-abdominal pressure not limited to any specific study or patient population. Findings were summarized based on the following information: general concepts of fluid management, physiology of fluid movement in patients with intra-abdominal hypertension, and data on associations between fluid administration and IAH. Results: We identified three randomized controlled trials (RCTs), 38 prospective observational studies, 29 retrospective studies, 18 case reports in adults, two observational studies and 10 case reports in children, and three animal studies that addressed associations between fluid administration and IAH. Associations between fluid resuscitation and IAH were confirmed in most studies. Fluid resuscitation contributes to the development of IAH. However, patients with IAH receive more fluids to manage the effect of IAH on other organ systems, thereby causing a vicious cycle. Timing and approach to de-resuscitation are of utmost importance, but clear indicators to guide this decision-making process are lacking. In selected cases, only surgical decompression of the abdomen can stop deterioration and prevent further morbidity and mortality. Conclusions: Current evidence confirms an association between fluid resuscitation and secondary IAH, but optimal fluid management strategies for patients with IAH remain controversial.

Keywords: fluid therapy; abdominal hypertension; abdominal compartment syndrome; open abdomen; crystalloids; colloids; hypertonic; resuscitation; maintenance; sepsis

1. Background

Over the past two decades, the pathophysiological consequences of intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS) have received more research and awareness. The Abdominal Compartment Society (WSACS, www.wsacs.org (accessed on: 26 May 2022)) has set out clear definitions for intra-abdominal hypertension (subclassified into primary and secondary) and abdominal compartment syndrome, including the importance of concepts such as abdominal perfusion pressure (APP) [1–4].

Elevation of IAP leads to compromise in several organ systems, including cardiovascular (decreasing preload, increasing afterload, and decreasing cardiac output), respiratory (elevated diaphragm, decreased compliance, decreased functional residual capacity), central nervous system (intracranial hypertension due to functional obstruction of cerebral venous outflow), renal (compression of both the renal veins and arteries), and the gastrointestinal system (GIT) [5–14]. The effect on the GIT is multiple and includes mesenteric vein compression, decreased perfusion, intestinal edema, bacterial translocation, and disruption of the gut microbiome and immune system [3].

The pathophysiological impact of elevated IAP on the various organ systems mimics a state like sepsis, with loss of vasomotor tone and dysfunction of the intercellular junctions of the endothelium. Fluid resuscitation is often the first choice to restore hemodynamic stability. However, administration of large volumes of intravenous fluids may paradoxically result in ACS. The increased abdominal pressure stimulates anti-diuretic hormone (ADH)

release, further promoting fluid retention [4]. Dabrowski et al., documented a significant correlation between IAP and extravascular water content in critically ill patients and patients undergoing prolonged elective surgery [5]. Reintam et al., showed that mortality among patients with secondary IAH was significantly higher than among patients with primary IAH [6], whereas a meta-analysis looking at various risk factors for IAH identified fluid balance as an independent predictor for IAH [7].

The effect of intravenous fluid administration on IAP has been studied, however, the effects of fluids on IAP in different patient populations and conditions remain largely unexplored.

The effect of pressures on neighboring anatomical compartments highlights the importance of appropriate management of patients with IAH or elevated pressures in adjacent compartments (abdomen, thorax, skull) [10–13]. In 2007, Thomas Scalea was the first to suggest the complex and constant interplay of elevated pressure between different compartments [8]. The poly-compartment syndrome (PCS) as "terminus technicus" coined by Malbrain has been well described in the medical literature [10–13]. Genuine PCS is a rare, but life-threatening condition, when two or more compartments have simultaneously elevated pressures. Releasing the pressure of one of the affected compartments usually improves the clinical scenario [15,16].

The goals of treatment for PCS are:

1. To reduce the pressure in the compartment by improving compliance (e.g., muscle relaxation) and, or opening different compartments (e.g., through escharotomy or decompressive surgery).
2. Individualized fluid management strategies and supportive therapy.
3. Apply the concepts of the four stages of fluid resuscitation (ROSE model, Figure 1) [17].
4. Avoid the adverse effects of ischemia-reperfusion after surgical decompression [11–13].

Figure 1. The four hits of shock. Graph showing the four-hit model of shock with evolution of patients' cumulative fluid volume status over time during the five distinct phases of resuscitation:

Resuscitation (R), Optimization (O), Stabilization (S), and Evacuation (E) (ROSE), followed by a possible risk of Hypoperfusion in case of too aggressive de-resuscitation. On admission patients are hypovolemic, followed by normovolemia after fluid resuscitation (EAFM, early adequate fluid management), and possible fluid overload, again followed by a phase going to normovolemia with late conservative fluid management (LCFM) and late goal directed fluid removal (LGFR) or de-resuscitation. In the case of hypovolemia, O_2 cannot get into the tissue because of convective problems; in the case of hypervolemia, O_2 cannot get into the tissue because of diffusion problems related to interstitial and pulmonary edema, gut edema (ileus and abdominal hypertension). Adapted according to the Open Access CC BY License 4.0 from Malbrain et al., with permission [17].

As the available data is scarce, this scoping review aims to describe the impact of fluid resuscitation on the development of intra-abdominal hypertension. Firstly, current knowledge on the pathophysiology of fluid administration is summarized, focusing on specific aspects related to increased IAP. Secondly, studies addressing fluid management in subjects with IAH are summarized and discussed.

2. Methods

Methods for inclusion, analysis and reporting of results were according to recommendations from the preferred reporting items for systematic reviews and meta-analyses (PRISMA).

Search Strategy

Two investigators performed a literature search for articles between 1950 and May 2021 using Scopus and PubMed electronic databases. We used the following search terms: ("abdominal hypertension" OR "abdominal compartment syndrome" OR "abdominal pressure") AND ("fluid therapy" OR "fluid resuscitation" OR "risk factor"). The search was limited to English-language articles. PubMed search formula included ("intra-abdominal hypertension" [All Fields] OR "intra-abdominal pressure" [All Fields]) OR "abdominal compartment syndrome" [All Fields]) AND ("fluid" [All Fields] OR "resuscitation" [All Fields]). Identified citations had their titles and abstracts independently screened for the relationship between fluid therapy and IAH (Figure 2). We used the following inclusion criteria: (1) No age limitation and animal studies included; (2) studies that examined the association between fluid resuscitation and IAH or ACS; (3) IAH diagnosed using trans-bladder pressure measurements; and (4) no limitation to the type of study design. Disagreements between investigators regarding study inclusion were resolved by consensus. Reference lists of these papers, and related articles featured in PubMed, were screened to identify additional studies not identified through the initial literature search.

The same two authors extracted the following data independently (as tabulated in the manuscript): (1) design and setting; (2) study participant diagnosis (for example, trauma, burn, severe acute pancreatitis); (3) type and amount of fluid administered; (4) IAP measurement in mmHg; (5) patient outcomes; (6) management/intervention of IAH or ACS.

All relevant studies underwent a full-text assessment, and data were extracted into tables according to the study type/design. Studies and hypotheses on pathophysiological mechanisms are summarized as narrative text. One hundred and three of the 657 potentially relevant publications identified during the literature search were included (Figure 2).
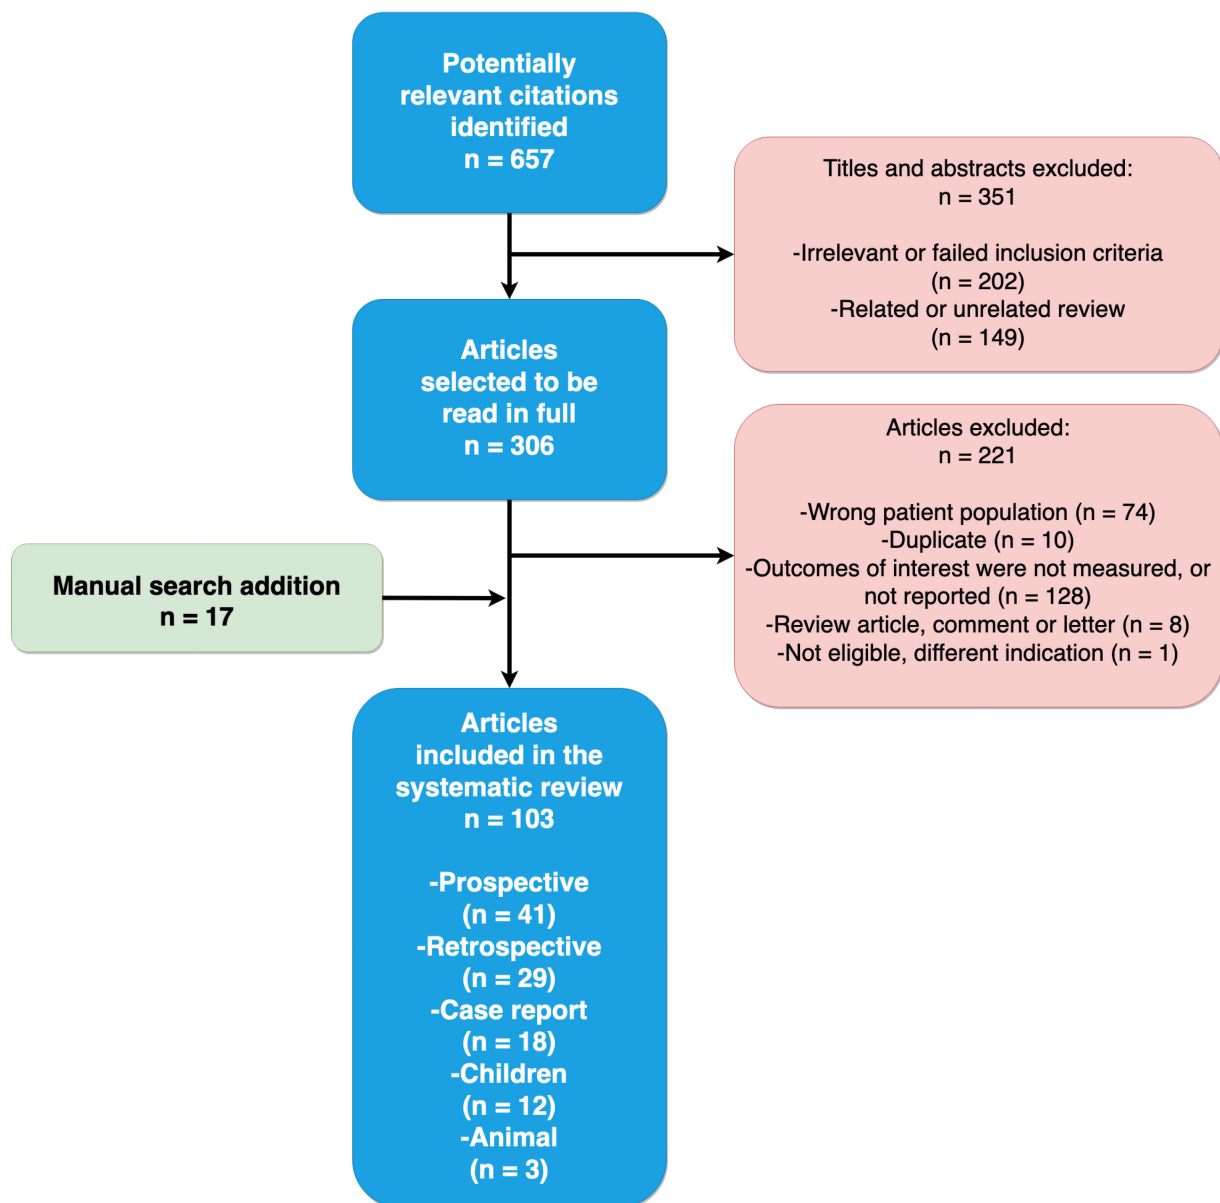

Figure 2. Flowchart of literature review and selection of included publications.

3. Results

3.1. Data on Associations between Fluid Administration and IAH

3.1.1. Study selection and characteristics

Among 764 unique citations, 103 studies enrolling 12015 critically ill adults, 107 critically ill children, and 104 animals met the inclusion criteria (Figure 2) [5,18–119]. Among the 103 included studies, 3 were randomized controlled trials (RCTs) (Table 1), 39 prospective observational studies (Table 1), 29 retrospective studies (Table 2), 17 case reports in adult patients (Table 3), two observational studies and 10 case reports in children (Table 4), and three animal studies (Table 5).

From the analyzed and discussed studies, twenty included burn patients [18–37], seven included severe acute pancreatitis (SAP) patients [40–46], thirty included trauma patients [38,39,47–71,73–75], fourteen included medical patients [70,72,76–87], seventeen included surgical patients [63,88–103], fourteen included medical-surgical (and critically ill) patients [5,104–116].

Pooled analysis was not possible because of the heterogeneity in study populations and data, and the lack of details on IAP measurement techniques.

Several above-cited studies have investigated the relationship between the volume of intravenous fluids administered and their effect on IAP. Most of these trials reported an association between the volume of intravenous fluids administered and the rise in IAP or the development of IAH.

3.1.2. Severe burn patients

There are nine prospective studies in 434 burn patients [18–26], six retrospective studies in 3171 burn patients [27–32], two case reports in adults [33,34], and three case reports in children [35–37] investigating the relationship between fluid resuscitation and ACS.

Prevalence

The reported prevalence of IAH ranged from 57.8% to 82.6% among patients with ≥20% total body surface area (TBSA) burned. Six of the nine studies reported ACS rates between 5.5 and 28.6% [18–26].

Resuscitation Fluids & Risk Factors

A capillary leak is common in critically ill patients and leads to interstitial edema. This can be a particular problem in burn patients who require large volumes of intravenous fluid resuscitation. There is a significant correlation between IAP and resuscitation volume [22,33,34]. A volume administration of > 250 mL/kg in the first 24 h is a risk factor for ACS, and this amount is known as the Ivy index [19]. Hypertonic lactated saline (HLS) resuscitation may reduce the risk of developing secondary ACS and is associated with a lower fluid volume when compared to Ringer's lactate (LR) solution [21,120]. Compared to colloid resuscitation, crystalloid resuscitation resulted in higher volumes of fluid per kilogram body weight, both in the first 24 h and during resuscitation with a significantly greater increase in IAP [23]. The implementation of 5% albumin in the first 24 h of resuscitation showed a trend towards less intravenous fluid. However, this did not translate into differences in the overall incidence of ACS, but it did improve outcomes [32]. Risk factors identified for acute kidney injury were IAH and the use of glycopeptides, vasopressors, and mechanical ventilation. Acute kidney injury was associated with increased 30-day mortality [25].

Management

Bladder pressure measurements should be performed after infusion of more than 25 mL during the acute resuscitation phase [18]. While IAH usually responds to medical therapy, the presence of ACS warrants escharotomy or surgical decompression of the abdominal cavity [18]. Non-resolution of IAH is related to a worse outcome [26,29,38].

Outcome

Mortality rates in the prospective studies varied from 18% to 82.6% [18–26]. The implementation of burn resuscitation guidelines can significantly lower mortality rates [18].

3.1.3. Severe acute pancreatitis

Severe acute pancreatitis (SAP) is a disease with a 30% mortality rate and is characterized by a systemic inflammatory response, pancreatic necrosis, and multiple organ failure [40]. Appropriate early fluid resuscitation is essential to prevent complications. Three RCTs [40,41,43], one observational study [42] (total of 295 patients), one retrospective study [44], and two case reports [45,46], investigated the relationship between intravenous fluids and IAH in SAP.

Prevalence

The incidence of ACS is lower when controlled fluid resuscitation is applied [40]. This was shown in an RCT where the incidence of ACS was 72.2% in the rapid fluid expansion group versus 32.5% in the controlled fluid expansion group [43].

Resuscitation Fluid and Risk Factors

The type of intravenous fluid used is important in the prevention of IAH. Resuscitation with colloids resulted in less IAH compared with crystalloids [41]. Using a combination of 0.9% saline, colloids, and glutamine is possibly a more efficient resuscitation strategy for SAP (by relieving inflammation and maintaining the intestinal barrier) than 0.9% saline [40]. Significant risk factors for the development of IAH in patients with SAP include the first 24-h fluid balance, number of fluid collections (which is included in the definitive Balthazar's CT score for severity stratification in acute pancreatitis), and serum calcium level [42].

Management

Early management of patients with SAP includes the initiation of CVVH to facilitate achieving a negative fluid balance and a subsequent reduction in IAH [44]. Abdominal decompression in patients with ACS may lead to a reversal of MOF [45,46].

Outcome

IAH is associated with a poor prognosis and an increased need for surgical interventions with associated morbidity and mortality. The reported mortality rate varied between 7.3% to 31.6% [41].

3.1.4. Trauma patients

Trauma patients frequently pose a fluid resuscitation challenge since they often require rapid intravenous fluid administration to treat hypovolemia. This may include red cell concentrate (RCC) and platelets. Rapid fluid administration, together with reperfusion injury and activation of inflammatory mediators, leads to increased capillary permeability and an increased risk of developing IAH and ACS [120,121]. There are seven prospective studies investigating the relationship between intravenous fluids and IAH in 1329 trauma patients [47–52,74], fourteen retrospective studies in 4233 trauma patients [38,39,53–62,69,75], five case reports [63–66,73], and five case reports in children [37,67,68,70,71].

Prevalence

The reported prevalence of ACS in the prospective studies varied between 8% and 36% (with a mean Injury Severity Score (ISS) range of 13–35) [47–52]. In a retrospective study by Zaydfudim et al., the implementation of a trauma exsanguination protocol significantly reduced ACS from 20% to zero [69]. Balogh found that the implementation of a standard resuscitation compared to a supranormal resuscitation reduced the incidence of IAH (20 vs. 42%) and ACS (8 vs. 16%) [53].

Resuscitation Fluid and Risk Factors

Trauma patients that develop ACS, as a complication of massive volume loading, receive significantly more crystalloids and blood products [48]. Aggressive crystalloid resuscitation should be minimized in severely injured patients. Neal et al., found that patients requiring massive transfusions (crystalloid resuscitation in a ratio greater than 1.5:1 per unit of RCC) were associated with a higher risk of MOF, ARDS, and ACS [50]. Although massive transfusion is associated with more complications, when blood products are delivered in a 3:2 ratio of RCC: FFP (red blood cells: fresh frozen plasma) and 5:1 for RCC: platelets, it is associated with a reduction in MOF and infectious complications, as well as an increase in ventilator-free days [63].

Management

Bladder pressures should be checked routinely when resuscitation volumes approach 10 L of crystalloid or ten units of packed red cells [60]. Following the resuscitation phase, fluid removal with diuretics or CVVH may restore euvolemia and may reduce IAP leading to improvement of organ failure [5,72,76].

Outcome

Trauma patients with ACS have more complications, mechanical ventilation, organ failure, and a longer length of stay. Mortality for this group varies between 6% and 54% [47–52,120]. Limiting crystalloids during resuscitation in trauma patients was associated with better outcomes and almost eliminated ACS [57,58].

3.1.5. Medical patients

Three prospective studies (188 patients) [85–87], two retrospective studies (143 patients) [78,79], three case reports in adult patients [72,76,77], two prospective trials (88 patients) in children [81,84], and four case reports in children [70,80,82,83] discuss fluid resuscitation in patients with sepsis.

Incidence

The observed incidence of IAH varied between 20 and 85%, and ACS developed in 25–28% of cases [78,85]. The incidence of IAH and ACS in a group of 40 medical ICU patients with a positive fluid balance of more than 5 L/24 h was high, with 85% developing IAH and 25% developing ACS [86].

Resuscitation Fluid and Management

In a prospective trial of 68 children, the replacement of crystalloid fluid resuscitation with albumin for refractory shock resulted in a smaller positive fluid balance, decreased morbidity, and improved outcomes [84]. Treatment (PAL therapy) that combined high levels of positive end-expiratory pressure (PEEP), small volume resuscitation with hyperoncotic 20% albumin (up to serum albumin levels of 30 g/L), and fluid removal using furosemide (a bolus of 1 mg/kg followed by continuous infusion at 10 mg/hour and titrated according to urine output) or renal replacement therapy with net ultrafiltration was associated with a reduction of extravascular lung water index (EVLWI) and IAP, was associated with improved clinical outcomes (better survival and faster weaning from mechanical ventilation) [87].

Decompressive laparotomy (open abdomen with silo bag) has been previously successful in medical patients [5,76]. Fluid removal with diuretics or CVVH may restore fluid balance and may reduce IAP, leading to improvement of organ failure [72].

Outcome

ACS is associated with a high mortality rate (52.8–77.4%) [78]. Moreover, Cordemans et al., concluded that there is a correlation between poor outcomes and a high capillary leak index (CLI), a positive fluid balance, high IAPs, high extravascular lung water indices (EVLWI), and low abdominal perfusion pressures (APP) [78]. The ACS-associated mortality rate in children was 16% [81].

3.1.6. Surgical patients

Six prospective studies (460 surgical patients) [92–97], four retrospective studies (189 patients) [88,89,98,99] and seven case reports (see Table 3) in adults [63,90,91,100–103], describe the association between fluid and ACS.

Incidence

Dalfino et al., showed how a positive fluid balance comprised one of three independent predictors for developing IAH (31.8%), together with baseline IAP and central venous pressure [104].

Resuscitation Fluid and Risk Factors

There is a significant positive correlation between increased IAP with a positive fluid balance and decreased IAP with a negative fluid balance [97]. A liberal fluid strategy, compared to a restrictive fluid strategy, is associated with a significantly higher

rise in IAP after surgery [94]. Furthermore, there was a strong correlation between IAP and extracellular water content in the liberal subgroup, which is in keeping with the hypothesis of fluid extravasation being one of the critical mechanisms in the development of IAH.

Makar et al., conducted an observational study in patients following open and endovascular repair of ruptured abdominal aortic aneurysms (rAAA). The results suggested that endovascular repair is associated with less intra-abdominal hypertension and host inflammatory response, less blood loss, blood transfusion, and total intraoperative intravenous fluid infusion compared to open repair [95]. In 25 patients with rAAA who underwent emergency EVAR [88], hypotension on arrival, transfusion of three or more units of red cell concentrate, and postoperative anemia were all significantly associated with the development of postoperative ACS.

Outcome

Patients with high IAP have more frequent renal failure, delayed postsurgical weaning from mechanical ventilation, and worse outcomes [92]. Reported mortality among patients with IAH was 53% [93]. The development of ACS after the repair of ruptured abdominal aortic aneurysms (rAAAs) results in increased mortality, especially in patients treated by endovascular aortic repair (EVAR) [89]. Intraoperative fluid requirements were significantly higher in EVAR patients who developed ACS than those without ACS. Furthermore, Leclerc et al., showed that in patients who underwent rAAA repair, patients with ACS appeared to have higher mortality [98]. For a positive prediction, they required three of the following eight factors: anemia, prolonged shock, preoperative cardiac arrest, body mass index >30 kg/m^2, massive fluid resuscitation and transfusions, severe hypothermia, and acidosis.

3.1.7. Mixed ICU patients

Twelve prospective studies (see Table 1) [5,104,107–116] (4213 patients) and 2 retrospective studies (71 patients) [105,106] describe fluid resuscitation in medical-surgical patients.

Incidence

The incidence of ACS varied between 2% and 12.9% [105,106]. The incidence of IAH is 25–30% on admission and 50% after the first week of ICU stay [115].

Independent Predictors for IAH

Fluid resuscitation and positive fluid balance are independent predictors for IAH [108]. Body mass index is significantly associated with the development of IAH [109]. Elevated vascular permeability due to a stress-related inflammatory response is associated with a positive fluid balance. It leads to extravascular fluid accumulation, which is likely to result in gastrointestinal tract edema and increased IAP [5].

Outcome

Mortality rates for IAH vary from 3 to 80% [110]. The grade of IAH is inversely related to outcome [111]. Biffl et al., showed that medical patients with ACS have a 100% mortality vs. 38% in trauma patients [104]. Similar results were seen in a retrospective (see Table 2) study that showed no significant differences in fluid resuscitation and bladder pressures between groups. However, there was a significantly higher incidence of MOF and a trend towards higher mortality in medical ACS [106]. Finally, the summary of findings of pediatric studies is presented in Table 4.

Table 1. Summary of findings of prospective studies on fluid administration and IAH.

Author	Year	Type of Study	Patients	Resuscitation Fluids	IAP (mmHg)	Results
Severe burn patients						
Ivy et al. [19]	2000	Prospective	n = 10 (7 IAH; 2 ACS)	IAH: volume of fluid 9 to 35 L 579 ACS: volume of fluid 33 to 48 L	IAP: 9 to 44	2 DL; 2 patients died
O'Mara et al. [23]	2005	Observational	Crystalloid (n = 15) vs. Plasma (n = 16)	561 mL/kg crystalloid 360 mL/kg plasma	Crystalloid: 32.5 Plasma: 16.4	Crystalloid group: - ↑ resuscitation volume/kg - ↑ IAH - ↑ end-organ damage
Oda et al. [21]	2006	Observational	HLS (n = 14) LR (n = 22) (≥40% TBSA)	Needed to maintain UO: HLS 3.1 ± 0.9 mL/24 h/kg/% TBSA vs. LR 5.2 ± 1.2 mL24 h/kg/% TBSA	HLS 14% vs. LR 50% developed IAH	HLS resuscitation can reduce risk of secondary ACS with lower fluid load than LR solution
Oda et al. [22]	2006	Observational	n = 48	ACS patients received 398.7 ± 105.5 mL/kg fluid the first 24 h after injury	IAP (49 ± 12 cm H_2O) ACS: n = 8	>300 mL/kg/24 h fluid resuscitation → ACS
Ennis et al. [18]	2008	Prospective	n = 56 BRG group n = 62 control group	>250 mL/kg volume in the first 24 h	Not reported	ACS and mortality significantly lower in BRG group (p = 0.03)
Ruiz-Castilla et al. [24]	2014	Observational	n = 25 (>20% TBSA)	10473 mL in pts with IAH vs. 4100 mL in no IAH (p = 0.03)	13 vs. 10	IAH pts: - IV fluid - organ failure - >extension of % TBSA
Wise et al. [26]	2016	Observational	n = 56	ACS 13.6 ± 16 L vs. No ACS 7.6 ± 4.1 L	IAH: n = 44 ACS: n = 16	Non-survivors: - ↑ incidence of IAH - ↑ total fluid intake - ↑ daily and cumulative fluid balance
Mbiine et al. [20]	2017	Observational	n = 64 (adults and children)	IAH in fluid overloaded patients: 16 vs. 13 IAH in patients not fluid overloaded: 10 vs. 9	Prevalence IAH: 57.8% 3.3 times increased risk of mortality with IAH Mortality with IAH: 82.6%	More IAH among the fluid overloaded patients, but difference not significant, probably due to small sample size
Talizin et al. [25]	2018	Prospective	n = 46 (38 IAH; 8 no IAH)	48 h fluid balance: With IAH: 5370 (3857–8828) mL Without IAH: 3894 (2411–5946) mL (p = 0.091)	Not applicable	IAH was associated with↑ mortality rate: 24 IAH + vs. 1 IAH − p = 0.016

Author	Year	Type of Study	Patients	Resuscitation Fluids	IAP (mmHg)	Results
				Severe acute pancreatitis		
Mao et al. [43]	2009	RCT	n = 76	Amount of crystalloid and colloid on admission day (mL): - Group I (rapid fluid expansion): - 4028 ± 1980 and 1336 ± 816 - Group II (controlled fluid expansion): - 2472 ± 1871 and 970 ± 633 Total amount of fluid sequestration within 4 days (mL): - Group I: 5378 ± 2751 - Group II: 4215 ± 1998	Incidence of ACS 72.2% in group I vs. 32.5% in group II	Total amount of fluid sequestration, rate of mechanical ventilation, incidence of ACS and mortality were significantly higher in group I
Du et al. [41]	2011	RCT	HES = 20 RL = 21	Total infusion volumes not significantly different between 2 groups	HES: 11.25 ± 2.35 RL: 17.08 ± 4.98	HES group ($p < 0.05$): IAP lower; more urine production, earlier negative fluid balance and fewer patients received mechanical ventilation
Ke et al. [42]	2012	Observational	n = 58	24 h fluid balance: IAH: 503 (373–1431) mL No IAH 74 (−31–409) mL	Median max IAP 13.1 mmHg 36 patients developed IAH 7 patients developed ACS	Risk factors for IAH include 24 h positive fluid balance (first day), number of fluid collections, and serum calcium level
Zhao et al. [40]	2013	RCT	n = 120	NS: 61.79 ± 7.61 mL/kg/day SH (NS + HES): 46.93 ± 12.38 mL/kg/day SHG (SH + glutamine) 44.75 ± 8.53) mL/kg/day ($p < 0.05$)	IAP in NS significant higher	Compared to the NS group: patients in the SH and SHG groups: - accessed the endpoint more quickly with less fluid volume (67.26 ± 28.53 mL/kg/d, 61.79 ± 27.61 mL/kg per day vs. 85.23 ± 21.27 mL/kg per day, $p < 0.05$). - incidence of renal dysfunction, ARDS, MODS and ACS lower

3.1.8. Animal data

We found eleven animal studies, of which three were suitable, reporting on resuscitation and secondary IAH (Table 5). Fluid resuscitation leads to IAH and venous congestion (or venous hypertension), resulting in gut edema and diminished gut contractility [117]. Melatonin may prevent deleterious effects related to fluid overload [118]. Extensive fluid resuscitation preserves cardiac output, urine output, and serum parameters (e.g., ALT, lipase, AP, lactate, creatinine) in pigs with ACS, but organ damage occurs (vicious cycle) [119]. Previous animal studies showed that IAH provokes the release of pro-inflammatory cytokines which may serve as a second insult for the induction of MOF [121]. This is illustrated in Figure 3.
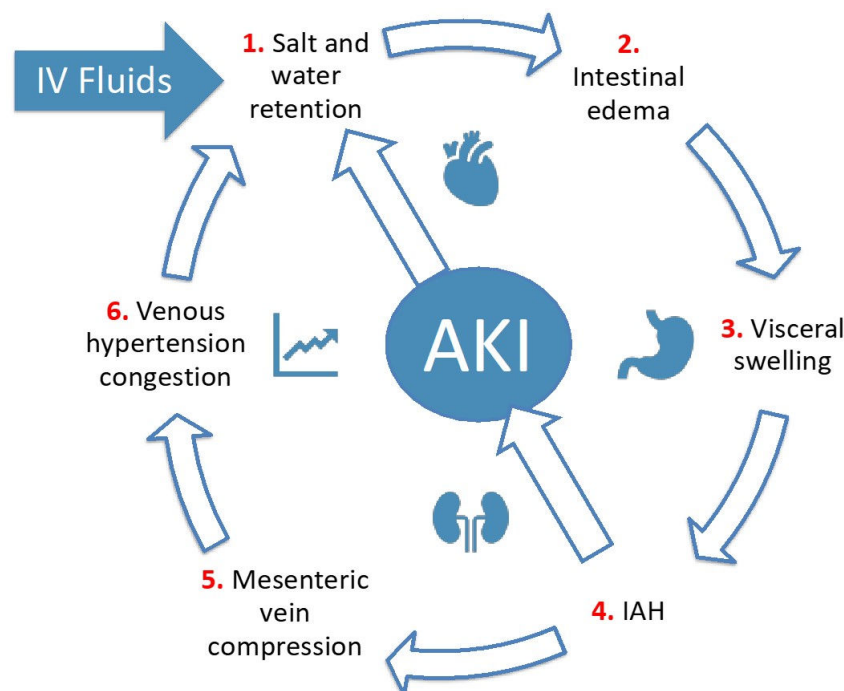

Figure 3. The vicious cycle of fluid resuscitation, abdominal hypertension and kidney injury. Adapted according to the Open Access CC BY License 4.0 from Malbrain et al., with permission [17]. AKI: acute kidney injury; IAH: intra-abdominal hypertension.

LR: Ringer's lactate solution, HES: hydroxyethyl starch, IAH: intra-abdominal hypertension.

4. Discussion

Existing studies and pathophysiological rationale support the association between fluid administration and IAH. However, current evidence does not allow clinicians to accurately identify specific fluid management strategies for patients with IAH. IAH often occurs in patients with sepsis, trauma, burns, and severe acute pancreatitis [122–124]. These conditions are united by an accompanying inflammatory response that often progresses to shock and requires ongoing intravenous fluid therapy. Addressing the underlying cause of the pathophysiological process is essential; however, in all these patients, fluid management remains a challenge. Avoiding hypovolemia as well as unnecessary excessive intravenous fluids and subsequent interstitial edema, with progression to IAH and ACS, is a difficult balance to achieve [125,126].

The origin of intravenous fluid therapy [127] dates back to the cholera outbreak in the 1830s. Resuscitation fluids are administered to restore intravascular volume and maintain tissue perfusion [17]. However, determining the volume status of a critically ill patient remains a diagnostic challenge [123]. Furthermore, the ideal synthetic intravenous resuscitation fluid does not exist. Both crystalloid and colloid solutions offer therapeutic options. Albumin is considered safe for use as a resuscitation fluid in most critically ill patients; however, in patients with traumatic brain injury, its use is associated with increased mortality [128]. The use of hydroxyethyl starch (HES) solutions is associated with increased rates of renal-replacement therapy and blood transfusion in patients with sepsis and surgery. The use of 0.9% saline has been associated with the development of metabolic acidosis and acute kidney injury.

Fluid movement through the microcirculation is partly determined by the imbalance between colloid osmotic and hydrostatic forces (Starling equation). Following this theory in IAH, an increase in microvenule blood pressure following venous compression reduces the difference in hydrostatic pressure, resulting in disturbance of microcirculatory fluid movement. The entire vascular endothelium is covered by the endothelial glycocalyx which consists of various proteoglycans, glycoproteins, and glycolipids. It which plays a vital role in the movement of fluids. The endothelial glycocalyx is semi-permeable to small molecules and ions and impermeable to molecules greater than 70 kDa [129,130]. The Starling equation has been revised to account for the sub-glycocalyx layer that contributes to a reflectance coefficient responsible for larger molecules staying intravascular. According to this revised Starling equation, the differences in plasma-sub-glycocalyx colloid osmotic pressure play a crucial role in trans-endothelial fluid movement [131]. The revised Starling equation has the sub-glycocalyx oncotic pressure replacing the interstitial oncotic pressure as a primary factor in transvascular fluid movement (Figure 4). The rule states that colloids such as albumin may delay transvascular fluid escape under selected conditions but will not pull fluids from the interstitium back into the vascular compartment; rather, albumin only returns to the intravascular compartment by the lymphatics [132,133]. A

decreased arterial pressure in conjunction with an increased venous pressure is frequently observed in patients with IAH. Increased pressure in venules may increase hydrostatic capillary pressure and augment transcapillary fluid extravasation causing loss of plasma volume. This is because of the dependence on differences in transendothelial pressure for the movement of fluid. Thus, the administration of colloid solutions to restore mean arterial pressure may maintain colloid osmotic pressure but increase hydrostatic capillary pressure, which may intensify fluid filtration. Crystalloid solutions decrease colloid osmotic pressure and increase hydrostatic capillary pressure, theoretically leading to higher fluid filtration than colloids [131]. However, IAH is often the result of several pathologies coinciding, damaging the glycocalyx and causing increased vascular permeability. As a result, both crystalloid and colloid solutions leak from the intravascular compartment into the interstitial space.

Experimental models have confirmed that when maintaining a normal MAP of approximately 65 mmHg (using vasopressors), fluid movement and reduction of plasma volume are more pronounced when the capillary permeability is disrupted versus normal conditions [134]. Interestingly, the plasma-reducing effect was lower in hypovolemic conditions compared to normovolemic subjects. These findings may suggest that the decrease in hydrostatic capillary pressure following hypovolemia leads to higher fluid retention in the intravascular space [135]. This effect may be disrupted by IAH; however, this hypothesis is yet to be confirmed.

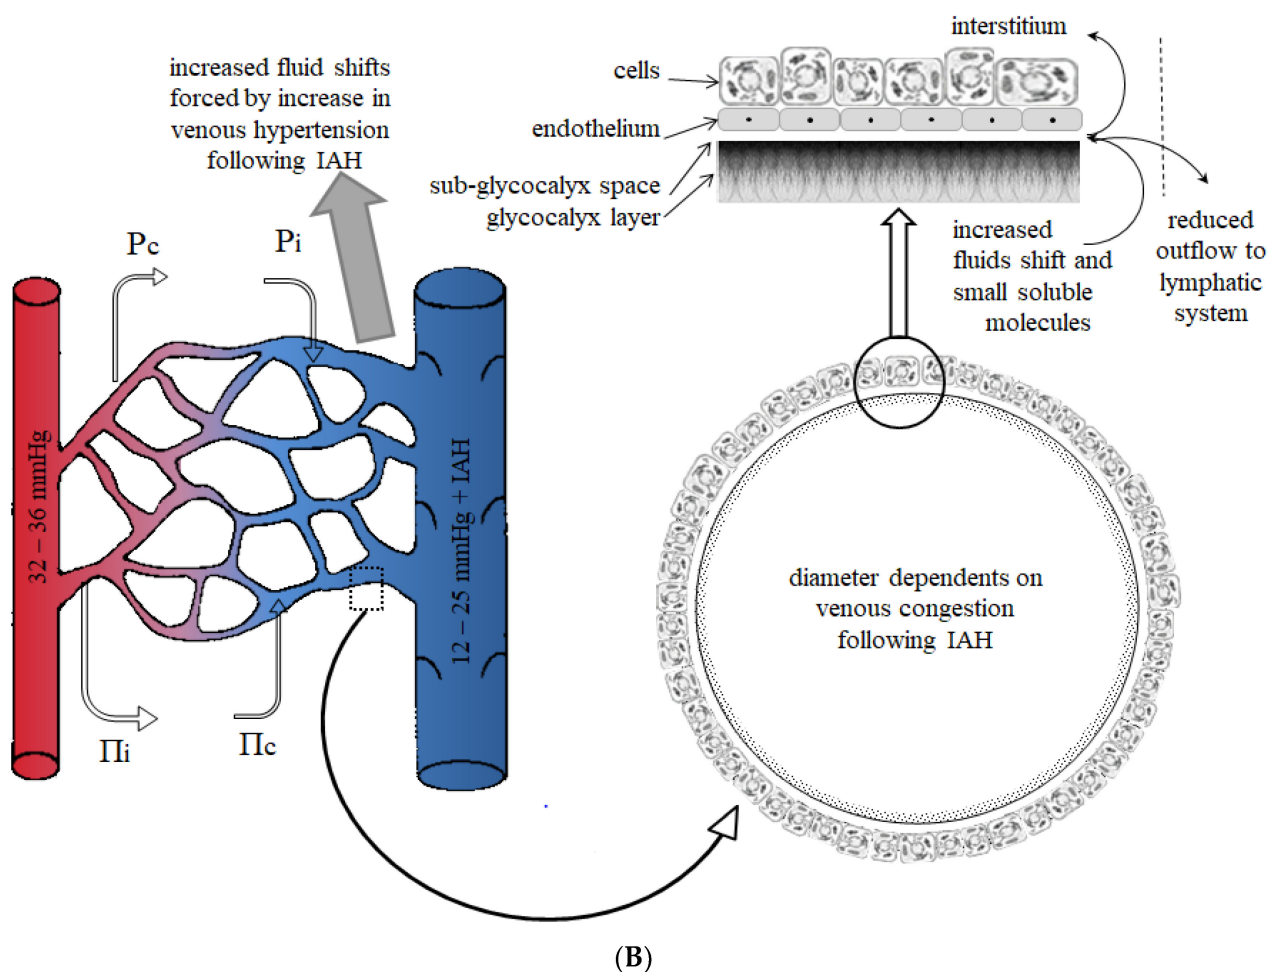

Figure 4. *Cont.*

(B)
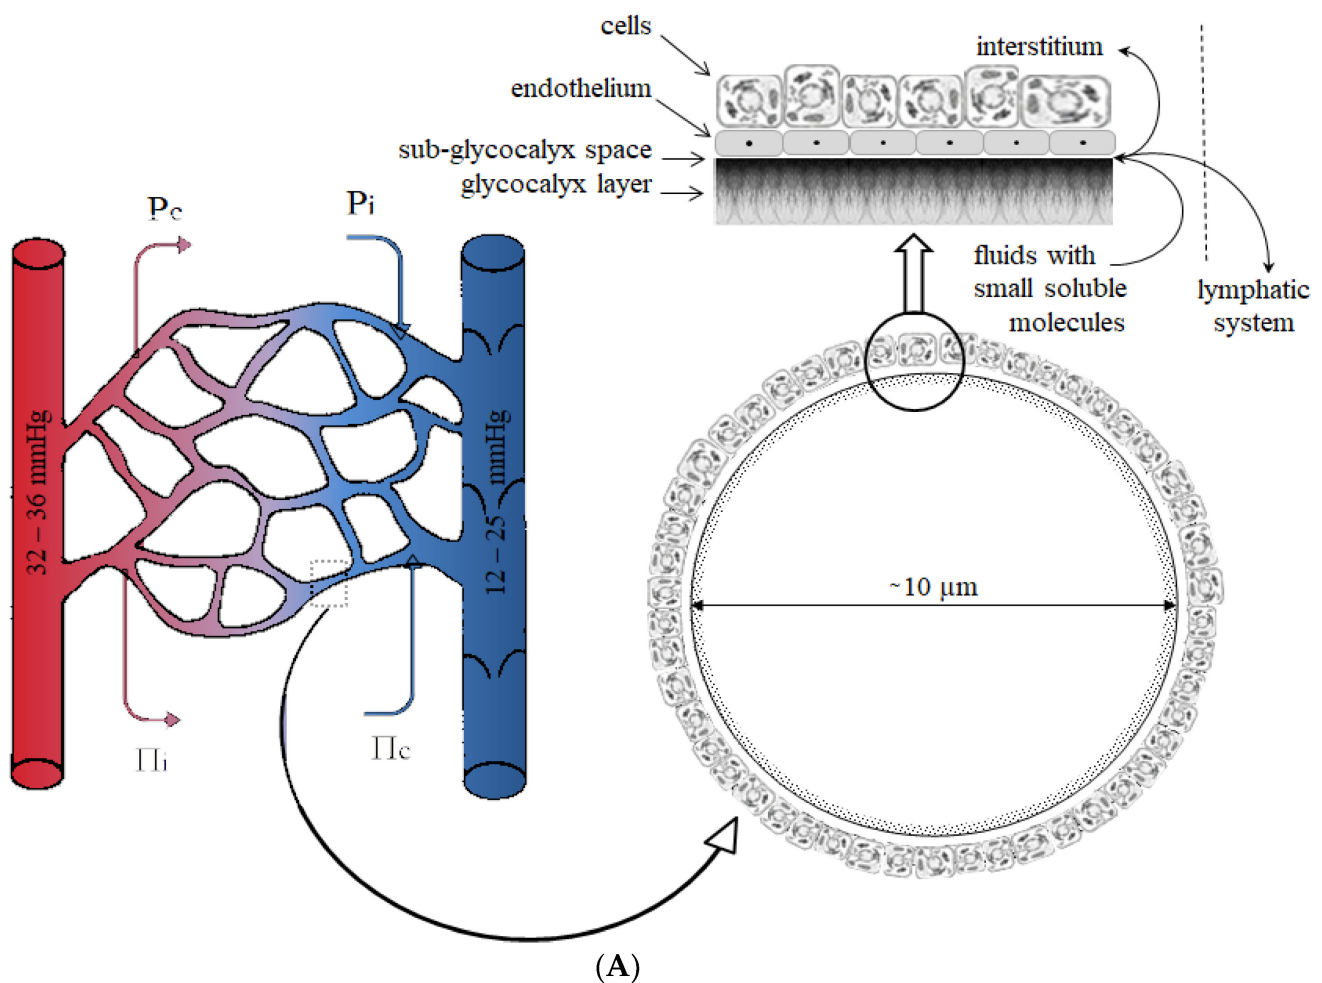

Figure 4. Fluid movement in normal conditions (**A**) and abdominal hypertension (**B**). The physiological movement of fluid is determined by the imbalance between hydrostatic and colloid osmotic pressures. It is best described by the revised Starling equation: $J_v = L_pA[(P_c - P_i) - \sigma(II_c - II_i)]$, where J_v is net fluid filtration, L_p the capillary hydraulic permeability, A the capillary surface area (which is available for fluids and small molecule filtration), σ the capillary reflection coefficient, P_c the capillary hydrostatic pressure, P_i the interstitial hydrostatic pressure, II_c and II_i the capillary and interstitial colloid osmotic pressures, respectively. Generally, P_c dependent on the differences between the arteriole hydrostatic pressure (P_A) and the venule hydrostatic pressure (P_V). This difference strongly corresponds to the hydraulic resistances in arterioles and venule (R_A and R_V, respectively), which was described by the Pappenheimer Soto-Riviera Equation: $P_c = (P_v [R_A/R_V] + P_A)/(1 + [R_A/R_V])$. According to this equation, every increase in P_A or P_V, as well as an increase in R_A/R_V (e.g., following intra-abdominal hypertension leading to venous congestion) or increase P_c. Under normal physiological conditions, the sub-glycocalyx colloid osmotic pressure strongly corresponds to interstitial pressure and its value ranges between 70% and 90% of the interstitial colloid pressure. Adapted from Levick et al. [133].

4.1. Type of Patients

The incidence of ACS and IAH differs across various patient populations, but with a high mortality rate, regardless of the population.

In severe burns, the systemic release of inflammatory and vasoactive mediators is responsible for a systemic capillary leak, intravascular fluid loss, and significant fluid shifts that should be managed with aggressive intravenous fluid resuscitation [136]. The implementation of the Parkland formula, developed by Baxter and Shires, reduced inadequate resuscitation in acute burn patients, which in turn significantly decreased burn mortality [137]. However, excessive intravenous fluid administration during resuscitation can also be detrimental and lead to an IAH prevalence as high as 82.6% in patients with more than

20% TBSA burned. Fluid creep is applied to a burn resuscitation, during which more fluid than predicted by standard formulas is administered. Increased fluid requirements may be necessary, but dangerous fluid creep is also caused by overly permissive fluid infusion and the lack of colloid supplementation [138]. Fluid creep is reported in 30% to 90% of patients with major burns [139,140]. Complications of fluid overload include extremity and abdominal compartment syndromes, respiratory failure, and ocular hypertension [138]. Factors that predispose to increased fluid requirements are inhalation injury, delay in resuscitation, and polytrauma or high voltage electrical injury [120]. The use of hypertonic saline, 5% albumin, and routine use of a burn resuscitation guideline are all measures to help limit unnecessary fluid resuscitation.

Severe acute pancreatitis is associated with high mortality rates [141], and the local and systemic inflammatory response in SAP leads to intravascular fluid depletion and extravascular fluid accumulation, leading to IAH and ACS. Generally, in patients with IAH, volume status is probably best monitored with volumetric preload indicators instead of barometric ones (such as central venous pressure and pulmonary capillary wedge pressure) [142]. The primary aim of fluid replacement is to improve circulatory dysfunction, which leads to tissue hypoperfusion, ischemia, and self-sustaining disease with persistent pancreatic injury, extra-pancreatic tissue damage, and organ failure [143]. Although many controversies exist about the ideal fluid strategy, an RCT performed on 76 patients with SAP showed that controlled, more conservative, fluid resuscitation offers a better prognosis in patients with severe volume deficit within 72 h of SAP onset [43,144]. Initiation of renal replacement therapy should be considered to help manage fluid accumulation and ACS.

In patients with SAP, sepsis, septic shock, or severe trauma, shock-induced endotheliopathy (SHINE) is responsible for endothelial cell and glycocalyx damage [145]. Disruption of the endothelial glycocalyx layer (EGL) can also be induced by rapid infusion of intravenous fluids (partly due to the release of atrial natriuretic peptide) and acute hyperglycemia [131]. In septic patients, interstitial oncotic pressure increases due to the capillary leak, leading to a reduction of the plasma-expanding efficacy of any infused fluid [131] and aggravating the development of tissue edema. More recently, it has been suggested that non-resuscitation fluids in critically ill patients may even have a more considerable absolute impact on cumulative positive fluid balance than resuscitation fluids. In contrast, unintentional fluid administration in the form of IV medications and concentrated electrolytes contributes to the phenomenon of 'fluid creep' [146].

Understanding the different phases of intravenous fluid management (Figure 1 represents the ROSE concept) is key to planning optimal fluid management. Hypovolemia should generally be treated with fluids and vasoplegia with vasopressors, but this balance is difficult to find in septic patients. Early vasopressors, in addition to fluid resuscitation, instead of fluids alone, may be necessary to avoid fluid overload [17,74,75,119,122,147,148]. The recent results of the CLASSIC trial have shed more light on this topic and showed that giving less fluids is not harmful [149]. On average IAH is observed in up to 43.5% of patients with severe sepsis [150].

4.2. Type of Resuscitation Fluids

Crystalloid fluids are the mainstay of fluid resuscitation; however, the findings of this review suggest alternative strategies require further investigation. A randomized controlled trial (RCT) compared HES with Ringer's lactate resuscitation in 41 patients with SAP. Resuscitation using colloids resulted in a lower IAP and reduced need for mechanical ventilation compared to those in which Ringer's lactate was used [41]. However, there is no evidence from RCTs that resuscitation with colloids in patients with trauma, burns, or following surgery, reduces the risk of death compared to resuscitation with crystalloids [151]. There is evidence of harm from synthetic colloids, especially synthetic starch solutions [152].

Balanced crystalloids may have advantages over 0.9% saline, possibly reducing inflammation, but no apparent effect on mortality or morbidity was demonstrated in patients

with SAP [153,154]. The recently conducted pragmatic SMART study (involving 15802 critically ill adults) showed that using balanced crystalloids for intravenous fluid administration resulted in a lower rate of composite outcomes, including death from any cause, new renal-replacement therapy, or persistent renal dysfunction than the use of saline [155]. Accordingly, several current guidelines suggest using balanced rather than unbalanced crystalloids in extensive volume replacements, surgical patients, and in SAP [142,154,156].

Several studies (SAFE [157], FEAST [158], ALBIOS [159]), evaluated the use of albumin as a resuscitation fluid. Except for patients with traumatic brain injury, evidence suggests that albumin is well tolerated as a resuscitation fluid. However, there is no evidence to suggest that albumin offers substantial outcome benefits over crystalloid solutions, albeit that their use may result in a less positive fluid balance [160–162]. This was demonstrated in an RCT by Martensson et al., where resuscitation with 20% albumin decreased resuscitation fluid requirements, minimized positive early fluid balance, and was not associated with any harm compared with 4–5% albumin. The use of 5% albumin in severe burn patients requires further research [161].

Only one retrospective study involving 114 patients incorporated IAP into the respiratory and fluid management concept. This study showed that using PAL treatment (PEEP set at the level of IAP, albumin 20%, followed by Lasix®) was able to keep the cumulative fluid balance in check with a significant drop in IAP, EVLWI, and rise in P/F ratio. This also resulted in faster weaning from the ventilator and improved survival compared to the matched control group [87].

Wang et al., conducted an RCT in 132 patients with SAP using fresh frozen plasma as a resuscitation fluid. Fresh frozen plasma shortens the duration of positive fluid balance, decreases the overall fluid balance within 72 h, reduces the duration of mechanical ventilation and admissions to ICU, and improves PaO_2/FiO_2 and mortality in severe acute pancreatitis [163].

Several animal studies proved that hypertonic saline (HTS) resuscitation improves hemodynamics [164–167]. HTS treatment allows smaller fluid volume resuscitation in the burn shock period and reduces the risk of low abdominal perfusion and secondary ACS 21]. The American Burn Association evaluated the efficacy of HTS in burn patients, however, the evidence in favor is equivocal. Additional studies are required to define the correct dosage and timing [168].

4.3. Fluid Resuscitation Strategies

The 4 D's of fluid therapy (drug, dosing, duration, and de-escalation) should be considered during the administration of resuscitation fluids [17,148]. Fluid requirements of critically ill patients tend to change throughout their illness, and fluid therapy should be adjusted to account for these changes. Therefore, we distinguish four phases of fluid administration (ROSE) (Figure 1): the Resuscitation phase, the Optimization phase, the Stabilization phase, and the Evacuation phase [17]. The ROSE concept may help to guide therapeutic decision-making [17].

Decisions regarding the administration of intravenous fluids should be guided by functional hemodynamic measurements, such as pulse pressure or stroke volume variation. They should not be solely based on increased lactate, low MAP, or oliguria (<0.5 mL/kg/hour) [169,170]. With the increased use of ultrasound as a bedside modality in both emergency and critical care patients, it is important to consider point-of-care ultrasound (POCUS) as an adjuvant tool for IAH and management of fluid strategies (Figure 5). POCUS during the first three days of admission improved clinical performance in IAH scenarios and fluid management [171].
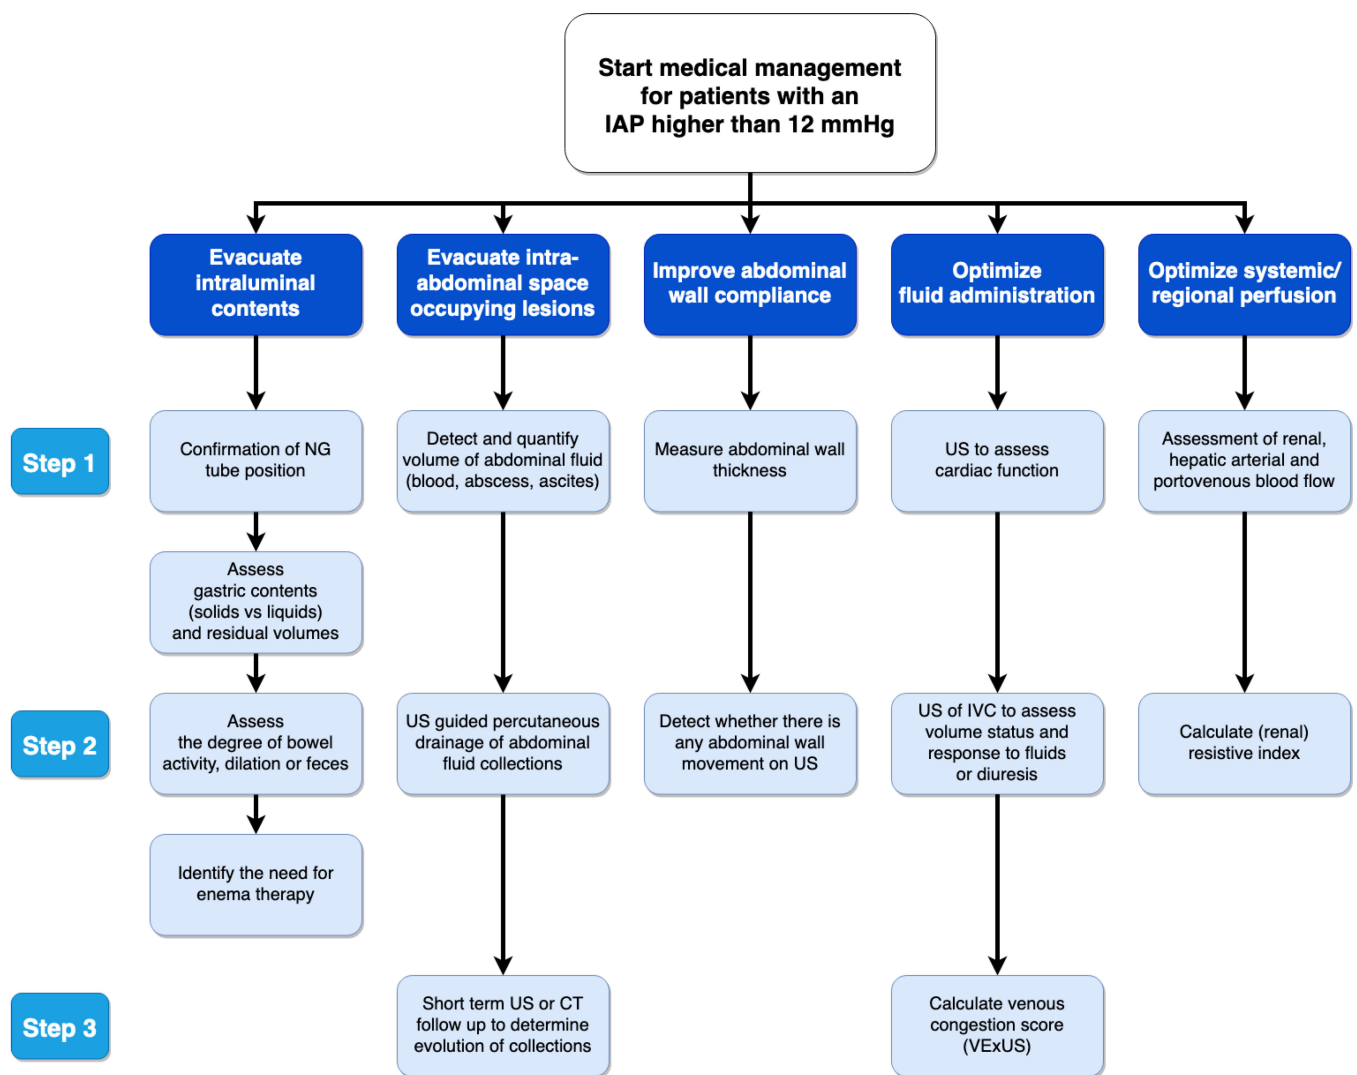

Figure 5. Potential use of POCUS according to WSACS medical management algorithm.

All of these factors should be carefully considered, to avoid the dangerous complications and vicious cycle of fluid accumulation, as illustrated in Figure 3 [172]. Fluid overload was identified as an independent risk factor for developing intra-abdominal hypertension [7,173].

The ideal rate at which fluid is administered appears to depend on how much it takes to maintain perfusion, and thus there is no clear guidance from the available literature. This would largely depend on the systemic inflammation, rate of fluid extravasation out of the intravascular compartment, and effects on cardiac function. An RCT involving 60 patients with acute pancreatitis, but without organ failure, that received either aggressive (20 mL/kg bolus followed by 3 mL/kg/h) or standard (10 mL/kg bolus followed by 1.5 mg/kg/h) resuscitation with Ringer's lactate solution. The rate of clinical improvement was more significant with aggressive hydration, and no patients developed signs of fluid overload [156]. Another RCT in 76 patients with SAP showed that rapid, uncontrolled fluid resuscitation (10–15 mL/kg/h or until a hematocrit <35% within 48 h) significantly worsened the rates of infections, ACS, the need for mechanical ventilation, and mortality [43]. Although these studies are relatively small, they suggest an optimum therapeutic range for fluid therapy. Further research in this field is required to help determine appropriate fluid resuscitation strategies in this group, particularly whether targeting a hematocrit is helpful [43].

4.4. Interventions with Potential Beneficial Effects That Need Further Investigation

Fluid requirements may be reduced by ascorbic acid, which has an apparent (osmotic) diuretic effect that may lead to hypovolemia and reduced inflammatory response [174]. This was shown in a prospective, randomized study where the use of high-dose ascorbic acid led to a significantly reduced amount of resuscitation volume [175].

Peritoneal resuscitation (PR) corrected many of the physiologic derangements that lead to eventual organ dysfunction, including endothelial cell dysfunction, tissue ischemia, reduction in capillary blood flow, derangements in fluid exchange, and electrolyte handling, and increased inflammatory mediators. Studies in trauma patients have shown that PR was associated with accelerated abdominal closure, reduced abdominal complications, and reduced mortality [176]. Further research in this field is required.

4.5. Limitations

Although the literature search was broad, it was limited to those studies published in English. There were potential sampling errors in the search terms, and the search was limited to Scopus and PubMed. Negative studies are less likely to be published and hence would not have come to our attention during the literature search. The studies included were also heterogeneous in their sampled populations and data, making pooled analysis impossible. Future studies should broaden the search to include other languages.

Final take-home messages on the relation between fluid resuscitation and IAH:

- There is a relationship between fluid resuscitation, fluid accumulation, and secondary IAH. This signal, from the limited number of RCTs, needs further confirmation.
- Crystalloids are associated with a more positive fluid balance and a greater likelihood of developing IAH compared to colloids or hypertonic solutions.
- Fluid resuscitation in IAH may preserve cardiac output, however, it does not prevent organ damage.
- Delivery of blood products in a 3:2 ratio of RCC: FFP (red blood cells: fresh frozen plasma) and 5:1 for RCC: platelets, may reduce MOF and infectious complications, and increase ventilator-free days [63].
- Fluid resuscitation leads to IAH and venous congestion (or venous hypertension), contributing to gut edema and diminished gut contractility.
- The relationship between fluid resuscitation, fluid accumulation, and secondary IAH holds in the setting of sepsis (capillary leak), severe burn injury, emergency surgery, and trauma with the presence of the deadly triad (coagulopathy, acidosis, hypothermia).
- Fluid removal with diuretics or CVVH may restore cumulative fluid balance and may reduce IAP. The time to initiate RRT in this setting remains unclear.
- Bladder pressure measurements should be performed after infusion of more than 25 mL during the acute resuscitation phase, and one should check for peak inspiratory pressures greater than 40 cm H2O.

The presence of IAH is associated with a poor prognosis. The presence of ACS warrants escharotomy or surgical decompression of the abdominal cavity, while IAH usually responds to medical therapy [48].

5. Conclusions

Intravenous fluid administration plays an essential role in developing IAH and ACS. Multiple pathophysiological mechanisms have been described, notably damaging the endothelial glycocalyx. Fluid balance has been identified as an independent risk factor in several clinical studies and can contribute to the development of IAH, venous congestion, gut edema, and diminished gut contractility. Evidence identifying the best resuscitation targets and management strategies regarding type, timing, and volume of fluids in patients with IAH is scarce. It is striking how there has been little advancement of new studies or

data in recent years, as the bulk of the literature is more than five years old. Therefore, further research is required to improve insights into this topic.
