Abstract

Background/Objectives: Cerebral small vessel disease (CSVD) is a leading cause of cognitive decline and dementia. The comparative prognostic value of MRI-based neuroimaging markers and genetic risk factors such as the APOE $\epsilon 4$ allele for cognitive outcomes remains uncertain. The objectives of this study were to estimate the pooled prevalence of cognitive impairment in CSVD, evaluate the associations of key neuroimaging markers (white matter hyperintensities [WMHs], cerebral microbleeds [CMBs], lacunes) and APOE $\epsilon 4$ with cognitive outcomes, and assess their diagnostic performance. **Methods:** This study included a systematic review and meta-analysis in accordance with PRISMA and MOOSE guidelines, searching five databases (2005–2025). Eligible studies included adults with CSVD and MRI-visible markers reporting cognitive outcomes (mild cognitive impairment [MCI], global cognitive impairment [GCI], all-cause dementia [ACD], vascular dementia [VaD], and Alzheimer's disease [AD]). Thirty-nine studies comprising 18,425 participants were included. Pooled prevalence and associations were estimated using random-effects models, and diagnostic accuracy was evaluated. Certainty of evidence was assessed using the GRADE framework. **Results:** The pooled prevalence of GCI in CSVD was 57% (95% CI: 51–62%), while MCI prevalence was 46% (95% CI: 42–51%). WMHs were strongly associated with VaD (OR 10.35, 95% CI: 7.32–14.64), lacunes with ACD (OR 3.18, 95% CI: 1.24–8.20), and CMBs with AD (OR 1.52, 95% CI: 1.04–2.24). APOE $\epsilon 4$ carriage increased the risk of GCI (OR 1.80, 95% CI: 1.41–2.29). Across markers, diagnostic sensitivity was low, specificity was moderate-to-high, and AUROC values were modest. GRADE certainty ranged from low to moderate, with the highest confidence for WMHs and VaD. **Conclusions:** CSVD-related MRI markers and APOE $\epsilon 4$ are significantly associated with both early and late cognitive outcomes, supporting the integrated vascular–neurodegenerative continuum. The limited diagnostic sensitivity and variable certainty of evidence highlight the need for harmonized definitions, lesion quantification, and multimodal imaging–genetic approaches to improve early detection and risk stratification of CSVD-related cognitive impairment.

Keywords: cerebral small vessel disease (CSVD); cognitive impairment; magnetic resonance imaging; APOE $\epsilon 4$; meta-analysis

1. Introduction

Cerebral small vessel disease (CSVD) encompasses a spectrum of microvascular brain pathologies that play a major role in the development of cognitive impairment and dementia [1,2]. Dementia ranks as the seventh leading cause of mortality globally [3] and is projected to increase in prevalence by 66% by 2050 [4]. CSVD is estimated to contribute to nearly 50% of all dementia cases [5], highlighting the urgency for more accurate diagnostic and predictive tools.

Magnetic resonance imaging (MRI) plays a crucial role in detecting the hallmark features of CSVD [6], including white matter hyperintensities (WMHs) [7], cerebral microbleeds (CMBs) [6,8], and lacunes [9]. The relative associations of these neuroimaging markers with different subtypes and stages of cognitive impairment remain inadequately characterized.

In addition to imaging, genetic risk factors, particularly the apolipoprotein E $\epsilon 4$ (APOE $\epsilon 4$) allele [10], have emerged as important contributors to cognitive decline in CSVD populations [11]. Yet, the combined utility of neuroimaging and genetic profiling in understanding and predicting CSVD-related cognitive outcomes is not well established [12]. Moreover, the mechanistic interplay between vascular injury and neurodegenerative processes, potentially mediated by APOE $\epsilon 4$ [13,14], warrants further investigation [15].

The NEUROGEN-SVD (NEUROimaging and GENetic determinants in Small Vessel Disease-related dementia) study was designed to address key gaps in understanding the relationship between CSVD and cognitive decline through a comprehensive meta-analysis and systematic review. Its objectives are threefold: first, to estimate the pooled prevalence of cognitive impairment among individuals with CSVD; second, to evaluate associations between MRI-based CSVD markers and cognitive outcomes; and third, to assess the impact of genetic risk factors, particularly the APOE $\epsilon 4$ allele, on cognitive impairment in CSVD populations.

2. Materials and Methods

2.1. Literature Search and Study Selection

The NEUROGEN-SVD study was conducted in accordance with PRISMA 2020 (Supplemental Table S1) and the Meta-analysis Of Observational Studies in Epidemiology (MOOSE) (Supplemental Table S2) guidelines. A comprehensive search strategy was employed across five databases, namely, PubMed, Embase, Cochrane Library, Scopus, and Web of Science, for studies published between January 2005 and March 2025. The search terms combined keywords and MeSH terms such as “cerebral small vessel disease,” “CSVD,” “MRI,” “APOE $\epsilon 4$,” “vascular cognitive impairment,” and “dementia.” The full search strategy is detailed in the Online Supplemental Information. Study screening and selection were guided by the PRISMA flowchart (Figure 1).

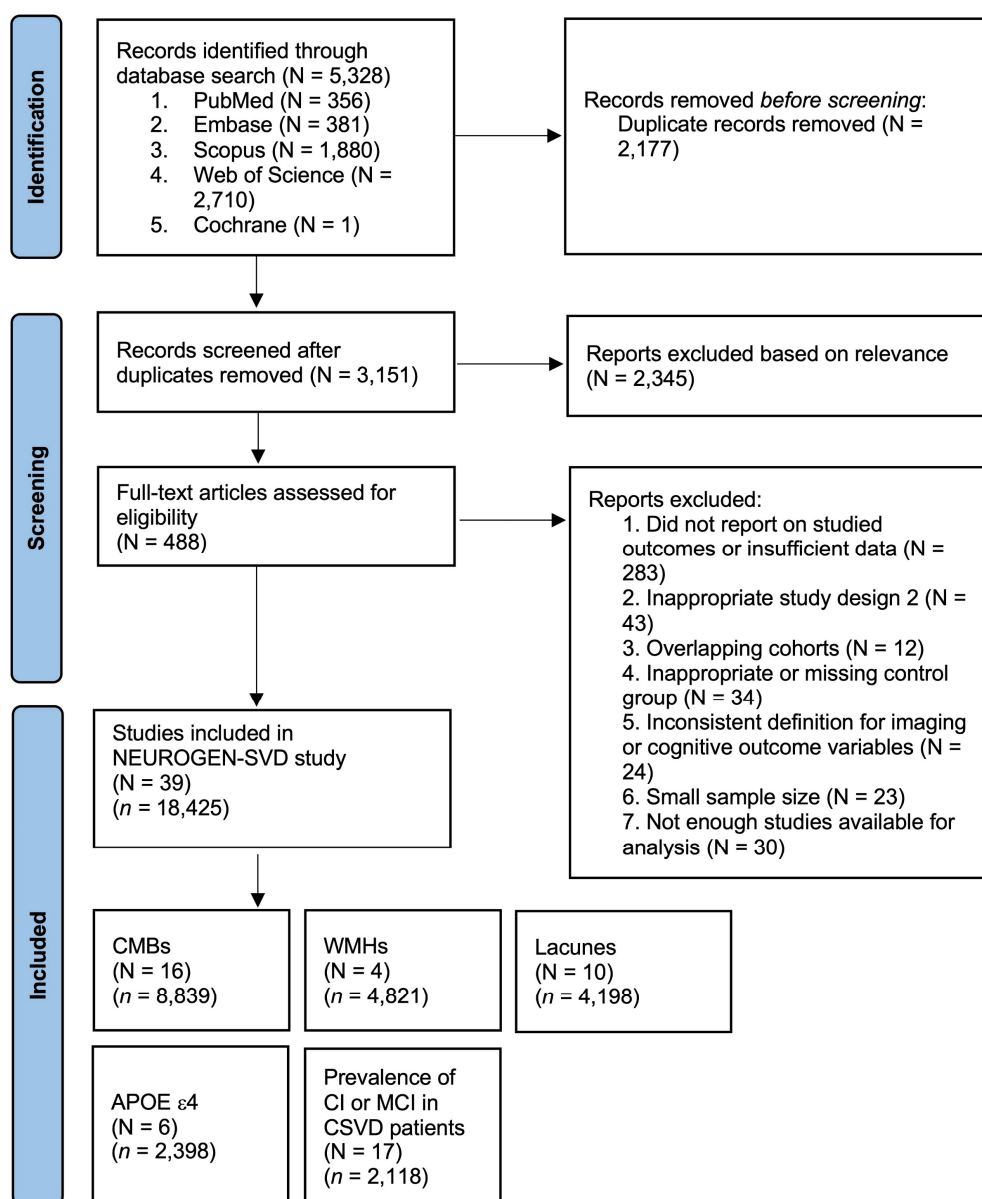

Figure 1. PRISMA flow diagram of study selection process for the NEUROGEN-SVD meta-analysis. The above illustration depicts the study selection flow according to the PRISMA guidelines, leading to the inclusion of studies in the meta-analysis. Abbreviations: NEUROGEN-SVD: NEUROimaging and GENetic determinants in Small Vessel Disease–related dementia; APOE: apolipoprotein E; GCI: global cognitive impairment; CMBs: cerebral microbleeds; CSVD: cerebral small vessel disease; MCI: mild cognitive impairment; WMHs: white matter hyperintensities.

2.2. Inclusion and Exclusion Criteria

Inclusion criteria encompassed (a) adult human subjects (≥ 18 years); (b) the presence of CSVD as defined by STRIVE criteria; (c) cognitive outcomes defined by clear diagnostic criteria; (d) comparative data between cognitively impaired and unimpaired individuals with respect to neuroimaging markers and/or APOE $\epsilon 4$ genotype; and (e) sample size ≥ 20 .

Exclusion criteria included non-English publications (unless translated); pediatric/animal studies; case reports; reviews; lack of full text; and studies without extractable data.

2.3. Definitions of CSVD Imaging Markers, Genetic Risk Factors, and CSVD

STRIVE [16] neuroimaging standards were used to define the selected imaging markers for CSVD. The markers with sufficient studies meeting eligibility criteria included in this meta-analysis were white matter hyperintensities (WMHs): the presence of moderate-severe (score of 2–3 on the Fazekas [17] scale); cerebral microbleeds (CMBs): the presence of any CMBs; lacunes: the presence of any lacunes; and genetic risk factor: APOE ϵ 4 carrier status. The criteria used to diagnose CSVD varied across included studies and are detailed in Tables 1–3.

2.4. Definitions of Cognitive Outcomes

The primary outcome was global cognitive impairment (GCI) as defined by each study. Secondary outcomes included mild cognitive impairment (MCI), all-cause dementia (ACD), vascular dementia (VaD), and Alzheimer's disease (AD). Imaging markers were WMH, lacunes, and CMBs; the genetic marker was APOE ϵ 4 carrier status. Where reported, WMH severity (Fazekas) was captured for dose-response analyses. The diagnostic criteria varied and are detailed in Tables 1–3.

2.5. Data Extraction

The titles and abstracts of all articles were initially reviewed using Endnote (Clarivate Analytics, London, UK) to exclude articles that did not meet the eligibility criteria. The remaining articles were comprehensively examined to determine their suitability for inclusion in the meta-analysis, in accordance with the defined eligibility criteria. Data extraction was conducted using a dedicated data extraction sheet, recording the following information from each study:

1. Baseline study demographics: author, country, publication year, cohort size, and study design.
2. Patient demographics: age and sex.
3. CSVD neuroimaging marker: WMHs, CMBs, and lacunes.
4. Genetic risk factor: APOE ϵ 4 allele carrier status.
5. CSVD neuroimaging marker and genetic risk factor characteristics: imaging marker score, CSVD diagnostic criteria, and MRI sequence.
6. Cognitive outcome: MCI, ACD, VaD, AD, and GCI.
7. Cognitive outcome characteristics: cognitive diagnostic criteria.

2.6. Methodological Quality Assessment of Included Studies

The methodological quality of included studies was assessed using the modified Jadad analysis (MJA) [18], which was completed independently by the primary researcher (Supplemental Table S1). The risk of bias due to funding was also evaluated by assessing the declaration of funding sources and conflicts of interest for each study (Supplemental Table S2).

2.7. Certainty of Evidence Assessment (NEUROGEN-SVD)

As part of the NEUROGEN-SVD study, the certainty of evidence for each cognitive outcome was evaluated using the Grading of Recommendations, Assessment, Development and Evaluations (GRADE) framework. Outcomes were assessed for risk of bias (study design limitations and diagnostic variability), inconsistency (heterogeneity in effect estimates), indirectness (applicability of study populations and outcome definitions), imprecision (width of confidence intervals and sample size), and publication bias (funnel plots, Egger's, and Deek's tests). A NEUROGEN-SVD Summary of Findings (SoF) table was constructed, presenting pooled effect estimates, absolute effects, and certainty ratings for the associations between CSVD neuroimaging/genetic markers and cognitive outcomes.

2.8. Statistical Analyses

All statistical analyses were conducted using STATA version 13.0 (StataCorp, College Station, TX, USA). Descriptive statistics were used to summarize baseline characteristics and key outcomes across included studies. Where necessary, means and standard deviations (SDs) were imputed from medians and interquartile ranges (IQRs) using the method described by Wan et al. [56].

The pooled prevalence of GCI among patients with CSVD was calculated using the metaprop command, implementing a random-effects model to account for inter-study variability. Exact binomial methods (cimethod(exact) and ftt) were used to derive 95% confidence intervals (CIs) for prevalence estimates. To estimate the associations between CSVD markers (neuroimaging and genetic) and cognitive outcomes, a random-effects meta-analysis using the DerSimonian-Laird (DL) method was applied via the metan package. Exploratory subgroup analyses were performed when at least three or more studies reported comparable data for a given exposure–outcome pair (e.g., imaging marker type and dementia subtype). However, stratified subgroup analyses by diagnostic framework, MRI modality, or cohort setting, as well as meta-regression, were not feasible because most studies did not report compatible covariates. Results were reported as pooled odds ratios (ORs) with corresponding 95% CIs and visualized using forest plots, which also detailed study weights and between-study heterogeneity.

The midas package in STATA was used to evaluate diagnostic performance. Summary receiver operating characteristic (SROC) curves were generated, and pooled estimates of sensitivity, specificity, and area under the ROC curve (AUROC) were reported. Statistical heterogeneity was assessed using the I^2 statistic (with the following thresholds: <30% = low, 30–50% = moderate, 50–75% = substantial, >75% = high) and Cochran's Q test. Between-study variance was estimated using Tau². Sensitivity analyses were performed using the metaninf function to assess the influence of individual studies on pooled effect sizes. Funnel plots were generated to visually assess asymmetry, and Egger's test was applied using the metabias and metafunnel packages to formally test for publication bias. Additional assessments included Deek's funnel-plot asymmetry test and Fagan's nomogram (implemented through the midas package) to evaluate potential bias in diagnostic accuracy estimates. All statistical tests were two-tailed, and $p < 0.05$ was considered statistically significant.

3. Results

3.1. Description of Included Studies

The systematic search across five major databases identified 5328 records. Following the removal of duplicates, 3151 unique records were retained for screening. Abstracts were reviewed for relevance, resulting in the exclusion of 2345 studies that did not address

CSVD, cognitive outcomes, or genetic risk factors. Full-text review of the remaining 488 studies led to the exclusion of 449 for the following reasons: absence of relevant outcomes or insufficient data ($n = 283$); inappropriate study design ($n = 43$); overlapping cohorts ($n = 12$); unsuitable control groups ($n = 34$); unclear or inconsistent definitions of imaging or cognitive variables ($n = 24$); small sample size below eligibility thresholds ($n = 23$); and imaging or genetic markers with insufficient numbers of studies for pooled analysis ($n = 30$).

Thirty-nine (39) studies met all inclusion criteria and were included in the final meta-analysis, encompassing 18,425 participants. Where data from the same database were available across multiple reports, priority was given to the largest or most recent cohort to avoid duplication. When data originated from the same database but were reported on distinct subgroups or different imaging/genetic markers, overlapping participants were excluded when calculating the total sample size.

Of the included studies, 16 reported on CMBs, 4 focused on moderate-to-severe WMHs, 10 on lacunes, 6 on APOE $\epsilon 4$ allele carrier status, and 17 provided prevalence estimates of cognitive outcomes in CSVD populations. These studies covered a wide geographic span, including Asian, European, and North American cohorts, enhancing generalizability. Clinical characteristics, diagnostic definitions, and cognitive outcome measures are detailed in Tables 1–3.

Pooled prevalence estimates of cognitive impairment outcomes are summarized in Table 4 and displayed as a forest plot in Figure 2. Associations between individual CSVD imaging markers and APOE $\epsilon 4$ status with cognitive outcomes are provided in Tables 5 and 6, organized by imaging/genetic risk factor (Table 5) and by cognitive outcome (Table 6). Corresponding odds ratios, study weights, and heterogeneity estimates are presented in Figures 3–6.

Table 4. Pooled prevalence of cognitive outcomes in CSVD patients: summary effects and heterogeneity.

| Sub-group | Studies (N) | Participants (n) | Summary Effects | | | | | Heterogeneity | | | |
|-----------|-------------|------------------|------------------|-------------------|-----------|-------|-------------|---------------|--------------------|-------------|----------|
| | | | Crude Prevalence | Pooled Prevalence | 95% CI | z | p | Q | I ² (%) | p (Q) | τ^2 |
| Overall | 16 | 2118 | 53.5% | 53% | 0.49–0.58 | 33.88 | $p < 0.001$ | 62.89 | 76.15 | $p < 0.001$ | 0.02 |
| GCI | 10 | 1518 | 55.9% | 57% | 0.51–0.62 | 28.48 | $p < 0.001$ | 42.15 | 78.65 | $p < 0.001$ | 0.02 |
| MCI | 7 | 766 | 46.3% | 46% | 0.42–0.51 | 31.02 | $p < 0.001$ | 8.91 | 32.67 | $p = 0.18$ | 0.00 |

Abbreviations: ACI: all-cause dementia; GCI: global cognitive impairment; MCI: mild cognitive impairment; 95% CI: 95% confidence interval; CSVD: cerebral small vessel disease. Notes: (1) “Crude prevalence” is the unweighted proportion; “Pooled prevalence” is the random-effects estimate; (2) Random-effects meta-analysis used the DerSimonian–Laird (DL) method; (3) Heterogeneity: Q (Cochran’s Q, χ^2 with $df = N - 1$); I² (% between-study variability); τ^2 (between-study variance, DerSimonian–Laird); (4) z and p are two-sided tests of the pooled effect; (5) One study with overlapping cohorts across MCI and GCI was excluded from the overall pooled estimate.

Although not the primary focus of this analysis, the diagnostic performance of imaging and genetic markers was also examined. These results, including pooled sensitivity, specificity, and AUROC estimates, are presented in Supplemental Table S5 and visualized through SROC curves in Supplemental Figures S1 and S2.

The methodological quality of included studies was appraised using a modified Jadad scale (Supplemental Table S3), while potential funding-related bias was assessed in Supplemental Table S4. Sensitivity analyses were conducted to evaluate the influence of individual studies on pooled results, with findings displayed in Supplemental Figure S3. To assess publication bias, funnel plots, Egger's regression, and Deek's funnel-plot asymmetry test were applied, with results presented in Supplemental Tables S6 and S7 and Supplemental Figures S4–S6. Fagan's nomogram analysis, included for exploratory purposes, is shown in Supplemental Figure S7.

3.2. Prevalence of Cognitive Outcomes in CSVD Patients

Sixteen studies [19–34], comprising a total of 2118 participants, were included in the pooled prevalence analysis of cognitive outcomes in patients with CSVD (Figure 2). The overall meta-analysis demonstrated that cognitive impairment was present in more than half of individuals with CSVD, with a pooled prevalence of 53% (95% CI: 49–58%; $z = 33.88$; $p < 0.001$) (Table 6; Figure 2). Between-study heterogeneity was substantial ($I^2 = 76.15\%$, $p < 0.001$), reflecting differences in study populations, diagnostic thresholds, and neuropsychological batteries. Figure 2 provides a stratified visualization of prevalence estimates by cognitive outcome subtype, specifically distinguishing between clinically defined GCI and MCI.

3.2.1. Prevalence of GCI in CSVD Patients

Ten studies [19,22,24–30,33] ($n = 1518$) specifically assessed the prevalence of GCI among CSVD patients. The pooled prevalence was 57% (95% CI: 51–62%; $z = 28.48$; $p < 0.001$), indicating that nearly three out of five patients with radiological evidence of CSVD exhibit a measurable global cognitive decline (Table 6; Figure 2). Heterogeneity across these studies was high ($I^2 = 78.65\%$, $p < 0.001$), suggesting variability in diagnostic methods and cohort characteristics. Some studies drew participants from memory clinics and stroke registries, whereas others used community-based samples, which may partly explain the observed inconsistency. Despite this heterogeneity, the direction of effect was consistent, underscoring GCI as a common and clinically significant outcome of CSVD.

3.2.2. Prevalence of MCI in CSVD Patients

Seven studies [19–21,23,31,32,34] ($n = 766$) examined the prevalence of MCI among CSVD patients. The pooled prevalence was 46% (95% CI: 42–51%; $z = 31.02$; $p < 0.001$), with only moderate heterogeneity ($I^2 = 32.67\%$, $p = 0.18$) (Table 6; Figure 2). This finding suggests that almost half of CSVD patients exhibit early-stage cognitive decline, often preceding overt dementia. The lower heterogeneity compared to GCI analyses may reflect more consistent use of standardized MCI criteria, such as Petersen's framework or modified NINDS-CSN definitions, across contributing studies.

3.2.3. Geographical Subgroup Analysis

When stratified by region, notable differences emerged. Asian cohorts (predominantly from China, Korea, and Singapore) reported a pooled prevalence of GCI around 60–65%, often higher than Western cohorts (Europe and North America), where prevalence estimates clustered between 45 and 55%. For MCI, Asian studies reported slightly higher prevalence (48–50%) compared to Western studies (42–45%), though heterogeneity was lower overall. This suggests that cultural and methodological differences may partly explain variability in GCI prevalence, whereas MCI prevalence estimates appear more stable across regions.

3.3. Association Between Neuroimaging Markers of CSVD and the APOE $\epsilon 4$ Allele with Cognitive Outcomes

3.3.1. Analysis by Imaging Marker

Cerebral Microbleeds (CMBs)

Sixteen studies [24,25,32,35–47] ($n = 8612$) examined the association between CMBs and cognitive outcomes. The presence of CMBs was significantly associated with MCI (OR 1.93, 95% CI: 1.48–2.51, $p < 0.001$), all-cause dementia (ACD; OR 1.92, 95% CI: 1.41–2.60, $p < 0.001$), vascular dementia (VaD; OR 4.70, 95% CI: 2.10–10.52, $p < 0.001$), and AD (OR 1.52, 95% CI: 1.04–2.24, $p = 0.033$). No statistically significant association was observed with overall GCI (OR 1.70, 95% CI: 0.92–3.16, $p = 0.091$) (Table 5; Figure 3). Heterogeneity ranged from moderate for MCI ($I^2 = 37.0\%$) and ACD ($I^2 = 49.2\%$) to substantial for VaD ($I^2 = 65.2\%$) and GCI ($I^2 = 70.3\%$), and was highest for AD ($I^2 = 80.8\%$).

White Matter Hyperintensities (WMHs)

Four studies [19,45,47,48] ($n = 4821$) investigated moderate-to-severe WMHs. Strong associations were found with MCI (OR 2.42, 95% CI: 1.57–3.74, $p < 0.001$), VaD (OR 10.35, 95% CI: 7.32–14.64, $p < 0.001$), and AD (OR 2.78, 95% CI: 1.27–6.09, $p = 0.011$) (Table 5; Figure 4). Heterogeneity was low for VaD ($I^2 = 0.0\%$), moderate for MCI ($I^2 = 48.8\%$), and high for AD ($I^2 = 84.6\%$). These findings suggest WMHs are a particularly robust imaging marker for vascular dementia and exert significant influence on both early and late cognitive outcomes.

Lacunae

Ten studies [24,25,37–40,45,49–51] ($n = 4198$) assessed lacunes, showing significant associations with MCI (OR 2.70, 95% CI: 1.25–5.84, $p = 0.011$), GCI (OR 2.41, 95% CI: 1.33–4.40, $p = 0.004$), and ACD (OR 3.18, 95% CI: 1.24–8.20, $p = 0.017$) (Table 5; Figure 5). Heterogeneity was substantial for GCI ($I^2 = 60.3\%$) and high for both MCI ($I^2 = 79.2\%$) and ACD ($I^2 = 85.4\%$). This likely reflects differences in imaging protocols, diagnostic thresholds, and classification challenges in distinguishing lacunes from enlarged perivascular spaces.

APOE $\epsilon 4$ Allele

Six studies [13,14,52–55] ($n = 2398$) examined APOE $\epsilon 4$ carrier status. Carriers had significantly higher odds of GCI (OR 1.80, 95% CI: 1.41–2.29, $p < 0.001$) (Table 5; Figure 6). Heterogeneity was substantial ($I^2 = 68.3\%$, $p = 0.017$), likely reflecting population differences in allele frequency and interactions with vascular risk factors.

3.3.2. Analysis by Cognitive Outcome

MCI: Twelve studies [19,32,38,40,41,44–49,51] ($n = 6904$) indicated that lacunes (OR 2.70, 95% CI: 1.25–5.84), WMHs (OR 2.42, 95% CI: 1.57–3.74), and CMBs (OR 1.93, 95% CI: 1.48–2.51) were significantly associated with MCI (Table 6).

GCI: Eleven studies [13,14,24,25,37,38,45,52–55] ($n = 3903$) showed that lacunes (OR 2.41, 95% CI: 1.33–4.40) and APOE $\epsilon 4$ allele status (OR 1.80, 95% CI: 1.41–2.29) were the strongest predictors of GCI. No significant association was observed with CMBs (OR 1.70, 95% CI: 0.92–3.16, $p = 0.091$) (Table 6).

ACD: Ten studies [35,36,38,39,42,43,45–47,50] ($n = 6429$) demonstrated significant associations with lacunes (OR 3.18, 95% CI: 1.24–8.20) and CMBs (OR 1.92, 95% CI: 1.41–2.60) (Table 6).

VaD: Six studies [36,39,43,45,47,48] ($n = 6214$) found very strong associations with WMHs (OR 10.35, 95% CI: 7.32–14.64) and CMBs (OR 4.70, 95% CI: 2.10–10.52) (Table 6).

AD: Eight studies [36,39,41,43–45,47,48] ($n = 8030$) reported significant associations with WMHs (OR 2.78, 95% CI: 1.27–6.09) and CMBs (OR 1.52, 95% CI: 1.04–2.24) (Table 6).

Publication bias was formally assessed using funnel plots, Egger’s regression, and Deek’s test. Visual inspection of funnel plots suggested small-study effects in some analyses, particularly for lacunes and APOE $\epsilon 4$. Egger’s test was significant in a subset of comparisons, while Deek’s test indicated asymmetry in diagnostic accuracy analyses for CMBs and lacunes but not for WMHs or APOE $\epsilon 4$ (Supplemental Tables S6 and S7; Supplemental Figures S4–S6).

These findings suggest that some degree of publication bias may be present, particularly for markers with fewer contributing studies, but overall results remained directionally consistent across sensitivity analyses (Supplemental Figure S3).

3.3.3. Diagnostic Performance of Neuroimaging Markers of CSVD and the APOE $\epsilon 4$ Allele for Cognitive Outcomes

Although the primary aim of this meta-analysis was to evaluate associations between CSVD markers and cognitive outcomes, the diagnostic performance of these imaging and genetic markers was also assessed. This exploratory analysis provides insight into their clinical utility for identifying patients at risk of cognitive decline. Data were available for all markers and cognitive outcome subtypes, with the exception of WMHs in relation to VaD and AD, where too few studies precluded pooled estimates.

Diagnostic performance was modest. Across markers, sensitivities were consistently low, ranging from 22% (95% CI: 0.13–0.35) for CMBs predicting AD to 50% (95% CI: 0.25–0.75) for CMBs predicting VaD. Specificities were generally moderate-to-high, spanning 66% (95% CI: 0.38–0.86) for WMHs with MCI to 90% (95% CI: 0.61–0.98) for lacunes with ACD. This pattern indicates that these markers are more reliable for ruling out cognitive impairment in unaffected individuals than for accurately identifying those at risk.

The APOE $\epsilon 4$ allele displayed similar limitations. Its sensitivity for predicting GCI was only 35% (95% CI: 0.29–0.41), whereas specificity was moderate at 76% (95% CI: 0.73–0.79). These values suggest that while APOE $\epsilon 4$ positivity raises the likelihood of cognitive decline, a large proportion of affected patients will not be captured by genetic screening alone.

Discriminatory ability, as assessed by AUROC, was also modest across most markers. AUROC values ranged from poor (0.44; 95% CI: 0.40–0.49 for lacunes with MCI) to moderate (0.81; 95% CI: 0.78–0.85 for CMBs with VaD). These results imply that while some combinations of markers and outcomes (such as CMBs with VaD) demonstrate reasonable discriminative potential, most fall short of thresholds typically considered clinically actionable. The full set of pooled sensitivities, specificities, likelihood ratios, and AUROC values is provided in Supplemental Table S5, with SROC curves shown in Supplemental Figures S1 and S2.

3.3.4. Certainty of Evidence (NEUROGEN-SVD)

The certainty of evidence across NEUROGEN-SVD outcomes ranged from low to moderate. Evidence supporting the association between WMHs and VaD was rated moderate certainty, reflecting a very strong effect size (OR 10.35) and low heterogeneity, despite variability in diagnostic criteria. Associations between WMHs and AD, as well as lacunes with GCI, were rated low certainty due to the heterogeneity and indirectness of outcome definitions. The APOE $\epsilon 4$ –GCI association was also rated low certainty, reflecting inconsistency across populations. The NEUROGEN-SVD Summary of Findings (Table 7) provides pooled effect sizes, absolute risk differences, and certainty ratings for each outcome.

Table 7. NEUROGEN-SVD GRADE summary of findings: certainty of evidence for CSVD imaging and genetic markers in cognitive outcomes.

| Outcome | No. of Studies (Participants) | Study Design | Relative Effect (95% CI) | Assumed Risk (control) | Risk with Marker | Absolute Effect (per 1000) | Certainty of Evidence | Reasons |
|---------------|-------------------------------|--|--------------------------|------------------------|------------------|----------------------------|-----------------------|--|
| CMBs → MCI | 8 (~2301) | Observational (meta-analysis, ran-dom-effects) | OR 1.93 (1.48–2.51) | 300 per 1000 | 450 per 1000 | 150 more per 1000 | ⊕⊕○○ Low | –1 risk of bias, –1 inconsistency, +1 moderate effect |
| CMBs → ACD | 9 (~5987) | Observational (meta-analysis, ran-dom-effects) | OR 1.92 (1.41–2.60) | 350 per 1000 | 500 per 1000 | 150 more per 1000 | ⊕⊕⊕○ Moderate | –1 risk of bias, +1 consistent effect |
| CMBs → VaD | 5 (~4399) | Observational (meta-analysis, ran-dom-effects) | OR 4.70 (2.10–10.52) | 200 per 1000 | 560 per 1000 | 360 more per 1000 | ⊕⊕○○ Low to Moderate | –1 heterogeneity, +1 strong effect |
| CMBs → AD | 7 (~5369) | Observational (meta-analysis, ran-dom-effects) | OR 1.52 (1.04–2.24) | 250 per 1000 | 360 per 1000 | 110 more per 1000 | ⊕⊕○○ Low | –1 imprecision, –1 heterogeneity |
| WMHs → MCI | 4 (~3513) | Observational (meta-analysis, ran-dom-effects) | OR 2.42 (1.57–3.74) | 300 per 1000 | 520 per 1000 | 220 more per 1000 | ⊕⊕○○ Low to Moderate | –1 risk of bias, –1 inconsistency, +1 effect size |
| WMHs → VaD | 4 (~1815) | Observational (meta-analysis, ran-dom-effects) | OR 10.35 (7.32–14.64) | 200 per 1000 | 740 per 1000 | 540 more per 1000 | ⊕⊕⊕○ Moderate | –1 diagnostic variability, +1 very strong effect, +1 low heterogeneity |
| WMHs → AD | 3 (~2621) | Observational (meta-analysis, ran-dom-effects) | OR 2.78 (1.27–6.09) | 250 per 1000 | 480 per 1000 | 230 more per 1000 | ⊕⊕○○ Low | –1 inconsistency, –1 indirectness, –1 imprecision |
| Lacunae → MCI | 4 (~1836) | Observational (meta-analysis, ran-dom-effects) | OR 2.70 (1.25–5.84) | 300 per 1000 | 560 per 1000 | 260 more per 1000 | ⊕⊕○○ Low | –1 heterogeneity, –1 indirectness |
| Lacunae → GCI | 5 (~1505) | Observational (meta-analysis, ran-dom-effects) | OR 2.41 (1.33–4.40) | 400 per 1000 | 610 per 1000 | 210 more per 1000 | ⊕⊕○○ Low | –1 marker misclassification, –1 heterogeneity |
| Lacunae → ACD | 4 (~1440) | Observational (meta-analysis, ran-dom-effects) | OR 3.18 (1.24–8.20) | 350 per 1000 | 640 per 1000 | 290 more per 1000 | ⊕⊕○○ Low | –1 inconsistency, –1 imprecision |
| APOE ε4 → GCI | 6 (~2398) | Observational (meta-analysis, ran-dom-effects) | OR 1.80 (1.41–2.29) | 400 per 1000 | 570 per 1000 | 170 more per 1000 | ⊕⊕○○ Low | –1 inconsistency, –1 indirectness |

Assumed risk (control) represents the baseline probability of the outcome in patients without the CSVD marker or APOE ε4 allele, expressed per 1000 individuals. This value was derived from the median or pooled control-group risk across included studies. Risk with the marker was calculated by converting the pooled odds ratio (OR) into an absolute risk using the following formula:

$$R_1 = \frac{OR \times R_0}{1 - R_0 + (OR \times R_0)} \quad (1)$$

where R_0 is the assumed baseline risk. Absolute effect is the difference between the risk with marker and the assumed risk, expressed as the number of additional (or fewer) events per 1000 individuals. Confidence intervals for absolute effects were derived by applying the same conversion using the lower and upper bounds of the pooled OR. Abbreviations: NEUROGEN-SVD = Neuroimaging and Genetic Markers in Small Vessel Disease study; GCI = global cognitive impairment; MCI = mild

cognitive impairment; ACD = all-cause dementia; VaD = vascular dementia; AD = Alzheimer's disease; WMHs = white matter hyperintensities; CMBs = cerebral microbleeds; OR = odds ratio. GRADE Working Group grades of evidence: ⊕⊕⊕⊕ High: Very confident that the true effect lies close to the estimate; ⊕⊕⊕○ Moderate: Moderately confident; true effect likely close but may differ; ⊕⊕○○ Low: Limited confidence; true effect may differ substantially; ⊕○○○ Very low: Very little confidence; true effect likely substantially different.

4. Discussion

This NEUROGEN-SVD study offers one of the most comprehensive syntheses to date on the relationship between CSVD, genetic susceptibility, and cognitive outcomes. Drawing on data from nearly 18,500 participants across 39 studies, the meta-analysis demonstrates that CSVD is a major driver of cognitive decline, extending beyond VaD to encompass the full spectrum of impairment, from MCI to ACD and AD. These findings reinforce CSVD as a central determinant of late-life cognitive trajectories and highlight its dual role in both vascular and neurodegenerative pathways.

While prior meta-analyses have largely focused on the prevalence of VaD, with estimates ranging between 36 and 67% depending on diagnostic criteria [57,58], few have examined GCI and MCI more broadly within CSVD populations. The current meta-analysis advances this field by estimating the pooled prevalence of GCI at 57% (95% CI: 51–62%), which is notably higher than a previous estimate of 44.1% [33]. It also reports an MCI prevalence of 46%, underscoring that CSVD is not only a driver of late-stage dementia but is also prominently involved in early cognitive decline. The relatively consistent prevalence of MCI across regions reinforces its potential as a stable and clinically meaningful early marker. The higher heterogeneity in GCI prevalence likely reflects the broad and variable definitions of GCI, which encompass a spectrum from MCI through to overt dementia.

These findings support an evolving model of CSVD-related GCI as a continuum. Rather than being defined solely by advanced pathology, CSVD contributes to subtle, microstructural tissue damage that disrupts connectivity long before overt lesion burden is visible [59]. This highlights opportunities for early intervention through aggressive management of vascular risk factors, lifestyle modification, and cognitive rehabilitation before cognitive deterioration becomes irreversible.

Previous meta-analyses have tended to examine individual imaging markers or their associations with specific cognitive domains [60] or dementia [61–63] outcomes. Based on current understanding, this is the first meta-analysis to systematically compare multiple CSVD markers (WMHs, CMBs, and lacunes) and genetic risk (APOE ε4) across a range of cognitive outcomes, from MCI through ACD, VaD, AD, and GCI. These results show that associations were generally stronger for later stages of impairment (ACD, VaD, and AD) than for MCI. This gradient is consistent with the progressive nature of CSVD, in which the cumulative burden of lesions disrupts white matter tracts and cortical–subcortical connectivity, gradually leading to widespread network dysfunction and cognitive impairment [59,64]. Weaker associations observed with MCI likely reflect that lesion burden in early stages may not have crossed the threshold needed to cause a clinically detectable decline.

Among individual markers, WMHs demonstrated the strongest and most consistent associations with cognitive outcomes, particularly VaD, where odds were increased more than tenfold. These findings align with prior evidence and reinforce the view of WMHs as markers of diffuse ischemia from chronic microvascular compromise, directly linked to sustained cerebral hypoperfusion [2,65]. Lacunes also showed significant associations across all outcomes, though with greater heterogeneity, likely reflecting variations in imaging protocols and challenges in distinguishing them from perivascular spaces [16]. CMBs demonstrated weaker associations overall, though they became significant in dementia outcomes,

suggesting their cognitive impact becomes apparent only once a threshold burden is reached [66].

The APOE $\epsilon 4$ allele was significantly associated with GCI, extending its relevance beyond AD risk alone. Emerging evidence suggests that APOE $\epsilon 4$ may exacerbate vascular injury through mechanisms such as neuroinflammation [67,68] and blood–brain barrier (BBB) dysfunction, independent of amyloid- β [69]. These observations support the Integrated Vascular–Neurodegenerative Continuum Hypothesis [2], which posits that vascular and neurodegenerative processes converge through overlapping pathways, lowering the threshold for GCI. This concept is reinforced by the observed associations between CSVD markers and AD, as well as by the influence of APOE $\epsilon 4$ across multiple cognitive subtypes. White matter lesions in AD are themselves heterogeneous: while many reflect chronic hypoperfusion [70] or amyloid angiopathy [71], others—particularly posterior periventricular lesions [72]—may arise from primary neurodegenerative mechanisms such as tau-mediated axonal degeneration [73–75]. Recognizing these dual etiologies is essential for interpreting the burden of WMHs in mixed dementias. Related biomarkers, including soluble low-density lipoprotein receptor-related protein-1 (sLRP-1), have been implicated in both vascular [76] and amyloidogenic cascades [77]; however, current data do not support sLRP-1 as a CSVD-specific marker distinct from AD or other comorbid conditions.

In addition to associations, the diagnostic performance of these markers was explored. Across neuroimaging and genetic measures, sensitivities were uniformly low, specificities were moderate-to-high, and AUROC values were modest. This indicates that while these markers have diagnostic weight when present, they lack sufficient sensitivity to serve as standalone screening tools. The findings underscore that cognitive decline in CSVD is unlikely to arise from isolated vascular or neurodegenerative processes but rather from their overlapping contributions [2]. This has two major implications. First, early systematic screening for GCI in CSVD populations is warranted, particularly targeting MCI, which appears as a consistent and robust early marker. Second, multimodal diagnostic strategies, integrating imaging markers, genetic risk, vascular burden, and clinical data, are needed to enhance diagnostic accuracy and risk stratification. Emerging BBB-permeability imaging, including arterial-spin labeling (ASL) [78], dynamic contrast-enhanced MRI [79], and novel PET tracers [80], provides complementary mechanistic insight into microvascular injury. Incorporating BBB metrics with WMHs and APOE status may refine early CSVD detection [81]. For Asian populations, where prevalence is higher, aggressive management of hypertension and diabetes may have particularly strong preventive effects.

High heterogeneity was observed across several outcomes, especially for associations involving GCI and AD with CMBs and lacunes. This likely reflects variation in imaging protocols, definitions of markers, diagnostic criteria, and study populations, which spanned hospital-based cohorts to community samples. Differences in adjustment for confounders and inter-rater reliability further contributed to variability. Funnel plots and formal bias tests suggested some small-study effects, particularly for lacunes and APOE $\epsilon 4$, though the overall direction of associations was consistent in sensitivity analyses. These observations highlight the pressing need for standardized imaging protocols, operational definitions of CSVD markers, and harmonized neuropsychological assessments to improve comparability and reduce heterogeneity. Insights from monogenic CSVD syndromes such as CADASIL (NOTCH3 mutations) [82,83] and COL4A1/2-related angiopathies [84] illuminate pure vascular pathways leading to cognitive impairment. Observations from these disorders, where lesion burden predicts cognitive decline independent of classical risk factors [85,86], reinforce the vascular mechanisms highlighted in our meta-analysis.

While this meta-analysis demonstrates robust associations between CSVD markers and cognitive outcomes, it is equally important to assess the certainty of these findings. Using the GRADE framework within NEUROGEN-SVD, the strengths and limitations of the available evidence were systematically evaluated. Certainty of evidence ranged from low to moderate, with the strongest confidence observed for WMHs as predictors of VaD, and lower confidence for associations with GCI and AD due to heterogeneity, diagnostic variability, and potential publication bias (Table 7). The NEUROGEN-SVD GRADE assessment therefore underscores both the strengths and gaps in the current evidence base. The most consistent and reliable signal was the strong association between WMHs and VaD, supported by moderate-certainty evidence, reinforcing WMHs as a key imaging marker of vascular cognitive outcomes. Associations with GCI and AD were downgraded to low certainty, reflecting variation in diagnostic criteria, imaging protocols, and study designs. These findings emphasize two key points: first, the directional consistency of associations across multiple markers suggests a genuine biological link between CSVD pathology and cognitive decline; second, the overall low-to-moderate certainty highlights the urgent need for harmonized definitions, standardized imaging protocols, and longitudinal multimodal studies. Incorporating lesion severity quantification, advanced neuroimaging, and genetic-vascular interaction models within the NEUROGEN-SVD framework will be critical for improving evidence certainty and advancing precision medicine strategies for CSVD-related cognitive impairment. Given the predominantly cross-sectional evidence, future multicenter cohorts with serial imaging and harmonized cognitive batteries are essential to track the transition from MCI to dementia, validate temporal associations, and test whether early multimodal risk scores predict trajectory.

Limitations

This meta-analysis has several limitations. First, pooled estimates could only be derived for WMHs, CMBs, and lacunes; data on other CSVD markers, such as cortical superficial siderosis and perivascular spaces, were insufficient. Second, most studies reported presence/absence rather than severity or burden of lesions, limiting the ability to assess dose-response relationships. Third, the analysis of APOE $\epsilon 4$ was restricted to GCI, as too few studies reported across other cognitive outcomes. Fourth, most included studies were cross-sectional, restricting insights into progression from MCI to dementia. Fifth, it was impossible to evaluate the combined predictive value of imaging and genetic markers simultaneously. Sixth, although limited exploratory subgroup analyses were performed, detailed stratified subgroup analyses and meta-regression could not be undertaken due to insufficient stratified reporting. No data imputation was attempted. Finally, substantial heterogeneity across studies likely influenced the precision and reliability of pooled estimates.

5. Conclusions

The NEUROGEN-SVD study provides one of the most comprehensive evidence syntheses to date linking CSVD imaging and genetic markers with cognitive outcomes. This meta-analysis confirms that WMHs, lacunes, CMBs, and the APOE $\epsilon 4$ allele are significantly associated with both early (MCI and GCI) and late (ACD, VaD, and AD) stages of cognitive impairment, reinforcing the concept of a vascular-neurodegenerative continuum. Certainty of evidence ranged from low to moderate, with the strongest confidence in WMHs as a predictor of vascular dementia. These findings highlight the urgent need for harmonized diagnostic frameworks, standardized imaging protocols, and longitudinal multimodal studies within NEUROGEN-SVD and related initiatives. Strengthening the certainty of evidence will be critical to advancing precision strategies for early detection, risk stratification, and prevention of CSVD-related cognitive decline.
