Abstract: In the present study, the effect of wet mechanical alloying (MA) on the glass-forming ability (GFA) of $Co_{43}Fe_{20}X_{5.5}B_{31.5}$ (X = Ta, W) alloys was studied. The structural evolution during MA was investigated using high-energy X-ray diffraction, X-ray absorption spectroscopy, high-resolution transmission electron microscopy and magnetic measurements. Pair distribution function and extended X-ray absorption fine structure spectroscopy were used to characterize local atomic structure at various stages of MA. Besides structural changes, the magnetic properties of both compositions were investigated employing a vibrating sample magnetometer and thermomagnetic measurements. It was shown that using hexane as a process control agent during wet MA resulted in the formation of fully amorphous Co-Fe-Ta-B powder material at a shorter milling time (100 h) as compared to dry MA. It has also been shown that substituting Ta with W effectively suppresses GFA. After 100 h of MA of Co-Fe-W-B mixture, a nanocomposite material consisting of amorphous and nanocrystalline bcc-W phase was synthesized.

Keywords: mechanical alloying; amorphization; nanocomposite; local atomic structure; X-ray scattering; X-ray absorption spectroscopy; magnetic properties

1. Introduction

Amorphous alloys are still the subject of scientific interest due to their outstanding combinations of physical, chemical, electrochemical and mechanical properties such as high tensile strength and hardness, extreme elastic strain limit [1,2], or higher corrosion resistance [3,4]. Amorphous materials are commonly prepared through the rapid solidification of melt, casting, forging, evaporation, sputtering and mechanical alloying. Co-based amorphous alloys represent a very attractive group of materials with interesting properties. For example, Co-Fe-Ta-B alloys show the best glass-forming ability (GFA) and wide supercooled liquid region of 70 K [5]. Along with this, they also exhibit the highest values of compressive yield strength (over 5000 MPa) [6]. Co-based amorphous alloys are also interesting for their magnetic behavior, like their high permeability, excellent soft magnetic properties, i.e., extraordinary low coercive force of 0.25 A/m, zero magnetostriction [7], giant magnetoimpedance [8] and excellent corrosion resistance [2]. For these reasons, they are the subject of lasting experimental study. Considering the mechanical properties, the best performance shows an alloy with the composition $Co_{43}Fe_{20}Ta_{5.5}B_{31.5}$ [6,9], which exhibits an ultra-high fracture strength of 5185 MPa, ultra-high Young´s modulus of 268 GPa and large supercooled region of 72 K [10]. In order to further enhance its GFA, a few research groups investigated the effect of alloying base alloy composition $Co_{43}Fe_{20}Ta_{5.5}B_{31.5}$ by selected elements: Mo, Si [6], Cr, Si [11], Nb [12], Cu, Si [13], Ni, Si [14], Ni, Nb, Si [15].

However, metallic glasses produced by rapid solidification techniques suffer from the limitations imposed by chemical composition range due to the mutual constrained solubility of elements or their largely different melting points. Reaching the precise composition can be difficult or impossible by melting, especially when pure elements have different physical properties. Another problem is that the alloy prepared by rapid quenching usually needs a critical cooling rate greater than 10^3 K/s, which means that the final dimensions of samples are restricted to a few millimeters. An effective approach to overcome the limited solubility of elements is represented by mechanical alloying. Mechanical alloying (MA) is a solid-state powder-processing technique involving the repeated welding, fracturing, and re-welding of powder particles in a high-energy ball mill [16]. MA enables the preparation of alloys with more varied constituents, which gives rise to unusual metallic glass compositions beyond the standard mutual solubility limits recognized in phase diagrams. The consolidation of amorphous powder via hot-pressing represents an alternative route to the preparation of bulk materials with the desired geometry. At present, increased attention is being paid to the preparation of materials of complex shapes using additive manufacturing [17]. Selective laser melting (SLM) is a powder bed fusion process that produces materials (microstructures) which exhibit morphological, compositional, or structural metastability due to their relatively high cooling rates (10^3–10^8 K/s). Since such high cooling rates are required to produce bulk metallic glasses, selective laser melting can be used for their preparation from an amorphous powder precursor [18,19].

This paper reports on the structural changes in $Co_{43}Fe_{20}X_{5.5}B_{31.5}$ (X = Ta, W) alloys synthesized by wet mechanical alloying using hexane as a process control agent. The main investigation line is to follow-up the amorphization of both alloys during mechanical alloying. Special emphasis is placed on the comparison of amorphization dynamics when substituting Ta with W. X-ray diffraction, transmission electron microscopy and X-ray absorption spectroscopy are used to characterize structural changes in short-range order during the process of mechanical alloying. The obtained results may be very useful for the large-scale production of amorphous powder precursors by mechanical alloying, which could be used for the production of net-shaped bulk materials by hot powder compaction or by additive manufacturing with selective laser melting.

2. Materials and Methods

2.1. Sample Preparation

The powder mixtures of nominal compositions $Co_{43}Fe_{20}Ta_{5.5}B_{31.5}$ (Ta-alloy) and $Co_{43}Fe_{20}W_{5.5}B_{31.5}$ (W-alloy) were prepared from crystalline elemental powders with a purity over 99.95 %. From each composition, a powder mixture with total weight of 20 g was prepared. Milling jars and balls used in mechanical alloying were made of steel. In order to ensure better mixing, each milling jar was filled with steel balls with a diameter 20 mm (6 pcs) and 10 mm (9 pcs). The ball-to-powder mass ratio was 14:1. Furthermore, each jar was filled with hexane up to two thirds of the jar height, so that milling balls and powders were completely covered. The powder mixtures were wet-mechanically alloyed using a RETSCH PM400 planetary ball mill. The milling speed was set to 200 rpm and the direction of rotation was changed every 5 min. The milling process was interrupted for 30 min after every 5 h of milling. Small amounts of powders for structural investigations were removed after 25, 50 and 100 h of milling. The samples were labeled according to their processing: Ta-25, Ta-50, Ta-100, W-25, W-50 and W-100 refers to Ta and W-alloy mechanically alloyed for 25, 50 and 100 h, respectively.

2.2. X-ray Scattering

High-energy X-ray diffraction (XRD) measurements were performed at the P02.1 undulator beamline of PETRA III electron storage ring (energy 6 GeV, current 100 mA) at DESY (Hamburg, Germany). The energy of the incident X-ray beam was fixed to 59.83 keV, which corresponds to a wavelength of λ = 0.2072 Å. Hard X-rays were used because a high resolution in real space, as desired for disordered materials, can be achieved

and the required data corrections are small, particularly for absorption. The diffraction experiments were carried out in the Debye–Scherrer geometry. Powder samples were put inside Kapton tubes (diameter 0.5 mm) and measured at room temperature by a collimated incident beam with a cross-section of 0.5 mm $\times$ 0.5 mm. Scattered photons were collected using a two-dimensional (2D) detector Perkin Elmer 1621 (2048 $\times$ 2048 pixels, pixel size 200 μm $\times$ 200 μm) carefully mounted orthogonal to the X-ray beam and 300 mm downstream from the sample. A CeO_2 standard powder sample was used to calibrate the sample-to-detector distance and tilt of the imaging plate relative to the beam path. The 2D XRD patterns were integrated with the q-space ($q = 4\pi \sin\theta / \lambda$, where θ is the half of a scattering angle) using the software package FIT2D [20]. The maximum value of magnitude of the wave momentum vector transfer q_{max} in this study was 18 Å^{-1}. The instrumental resolution function (IRF), describing the behavior of the peak broadening (full-with at half maximum, FWHM) as a function of the diffraction angle 2θ, was fitted to the Caglioti formula [21], $FWHM^2(\theta) = U\tan^2\theta + V\tan\theta + W$, where U, V and W are fitting parameters characterizing the instrument. The IRF was determined by measuring standard materials such as LaB_6 under the same experimental and geometrical conditions as the studied materials. The peak profiles of the standard material and studied materials were fitted with a Gaussian function. Experimental peak widths β_{exp} were corrected for the instrumental broadening, β_{ins}, using the equation $\beta = \sqrt{\beta_{exp}^2 - \beta_{ins}^2}$. About five independent measurements on each sample with an exposure time of 15 s were averaged to attain optimum counting statistics. Scattering intensity profiles $I(q)$ were corrected for absorption and background scattering. The total structure factor $S(q)$ was obtained from the normalized elastically scattered intensity, $I_{coh}^{eu}(q)$, using standard procedures described in references [22,23] by applying the Faber–Ziman formalism [24], $S(q) = 1 + I_{coh}^{eu}(q) - \langle f^2 \rangle / \langle f \rangle^2$, where $\langle f^2 \rangle = \sum_{i=1}^{n} c_i f_i^2(q)$, $\langle f \rangle^2 = [\sum_{i=1}^{n} c_i f_i(q)]^2$, in which c_i and $f_i(q)$ are the atomic concentration and atomic scattering factor [25] of the atomic species of type i (i = Co, Fe, Ta/W, B). The total structure factors $S(q)$ and corresponding pair distribution functions $G(r)$ were derived from experimental data using the program PDFgetX2 [26]. Selected $G(r)$ functions were analyzed by means of the real space fitting approach implemented in the software package PDFgui [27].

2.3. Transmission and Scanning Electron Microscopy

The structure of powder samples was investigated by Transmission Electron Microscopy (TEM). For TEM observations, the JEOL 2100F UHR microscope equipped with the Schottky FEG source and operated at 200 kV acceleration voltage was used. Powdered samples were dispersed in pure ethanol and ultrasonicated at varying frequencies for 480 s. Drops of solutions were placed on a copper support grid covered by lacey carbon film and dried out in a high vacuum (10^{-2} Pa) for several hours. Before TEM observations, the grids containing the sample were cleaned twice in a plasma cleaner Fischione M1020 for 17 s. Besides the image observations performed in a high-resolution bright field, the structure of samples was analyzed by Selected Area Diffraction (SAD). Scanning electron microscope (SEM) TESCAN Vega 3, equipped with the energy-dispersive X-ray (EDX) silicon drift detector Oxford Instruments X-Max 50, was used to check samples' chemical compositions after mechanical alloying. The thermionic gun of the microscope was powered by 10 kV acceleration voltage.

2.4. X-ray Absorption Spectroscopy

Extended X-ray absorption fine-structure (EXAFS) measurements were performed at the beamline P65 of PETRA III electron storage ring at DESY (Hamburg, Germany) [28]. EXAFS data were collected in transmission mode at the Fe-K (7112 eV), Co-K (7709 eV), Ta-L_3 (9881 eV) and W-L_3 (10,207 eV) edges using a fixed exit double crystal Si(111) monochromator. X-ray intensities were monitored using ionization chambers filled by gases, the type and pressure of which were adjusted to the corresponding energies. The energy calibration for Co, Fe, Ta and W was monitored using reference foils materials measured simultane-

ously with the sample. All spectra were energy-calibrated with respect to the first peak in the derivative spectrum of respective reference foil. Energy range of X-ray absorption scan $\mu(E)$ was 200 eV below the respective absorption edge energy E_0 with the upper boundary 530–1000 eV above. In case of Fe-K, Co-K, Ta-L$_3$ and W-L$_3$ edges the respective $\mu(E)$ scans were done 530 eV ($k_{max} = 11.8\,\text{Å}^{-1}$), 860 eV ($k_{max} = 15\,\text{Å}^{-1}$), 990 eV ($k_{max} = 16.1\,\text{Å}^{-1}$) and 1000 eV ($k_{max} = 16.2\,\text{Å}^{-1}$) above the absorption edge, respectively. The values in brackets indicate corresponding maximum k range (where $k^2 = 2m_e(E - E_0)e/\hbar^2$ in which m_e is the electron mass, E is energy in eV, e is the elementary charge and $\hbar$ reduced Planck's constant). In order to achieve a good counting statistics, measurement of each sample was repeated at least 5 times. All data processing operations and fitting of EXAFS spectra were carried out using the software package DEMETER [29].

2.5. Magnetic Measurements

The saturation magnetization M_S and coercivity H_c of the mechanically alloyed powders were determined from magnetization loops traced in a magnetic field with maximum induction of $\mu_0 H = 1.8$ T using a vibrating sample magnetometer VSM-LakeShore 735. All magnetic measurements were performed at room temperature. Temperature dependence of magnetization in constant magnetic field with induction of $\mu_0 H = 200$ mT was measured using a Faraday magnetic balance.

3. Results and Discussion

3.1. X-ray Diffraction

Figure 1 shows a comparison of XRD patterns for Ta- and W-containing alloys at different stages of mechanical alloying. In case of the Ta-alloy, it can be seen (Figure 1a) that, after 25 h of milling, its XRD pattern exhibits rather broad features due to the presence of amorphous phase. Additionally, it shows a set of distinct peaks which were assigned to Co$_{21}$Ta$_2$B$_6$ (fcc, Fm$\bar{3}$m, ID-1511583) and Fe$_{1.8}$B$_{0.2}$ (bcc, Im$\bar{3}$m, ID-1511091). The phases were identified with the help of the Crystallographic Open Database (COD) [30]. It should be noted here that Bragg peaks belonging to these two phases are very broad, which indicates their nanocrystalline state. With further increases in milling time their presence diminishes, and after 100 h, a material with completely amorphous structure is achieved. Authors of previous work [31] have shown that the MA of a very similar alloy composition Co$_{40}$Fe$_{22}$Ta$_8$B$_{30}$ could not reach a fully amorphous material, even after 200 h of dry milling under an argon protective atmosphere. Our results indicate that using hexane as a process control agent during wet MA results in the formation of fully amorphous Co-Fe-Ta-B powder material at a much shorter milling time (100 h) as compared to dry MA [31]. A very recent work of Msetra et al. [32] reported the synthesis of fully amorphous Co$_{60}$Fe$_{18}$Ta$_8$B$_{14}$ alloy after 100 h of dry mechanical alloying.

XRD patterns of the W-alloy (Figure 1b) show a qualitatively different behavior compared to the Ta-alloy. First, more intense and sharper Bragg peaks are observed after 25 h of mechanical alloying. All peaks were identified and can be assigned to the following crystalline phases: W (bcc, Im$\bar{3}$m, ID-9011610), Co$_3$Fe (bcc, Im$\bar{3}$m, ID-1524167), Fe$_2$B (tetragonal, I$\bar{4}$2m, ID-1511152) and tiny traces of B (tetragonal, P4$_2$/nnm, ID-9012310). With increasing milling time, all Bragg peaks become less intense and much broader. After 100 h of mechanical alloying, the final phase composition can be characterized as a mixture of the amorphous phase with nanocrystalline bcc-W and tiny traces of residual phases Co$_3$B and Fe$_2$B. It is evident from the results presented in Figure 1 that substituting Ta with W significantly reduces amorphization dynamics, and achieving a fully amorphous state would require a much longer milling time.
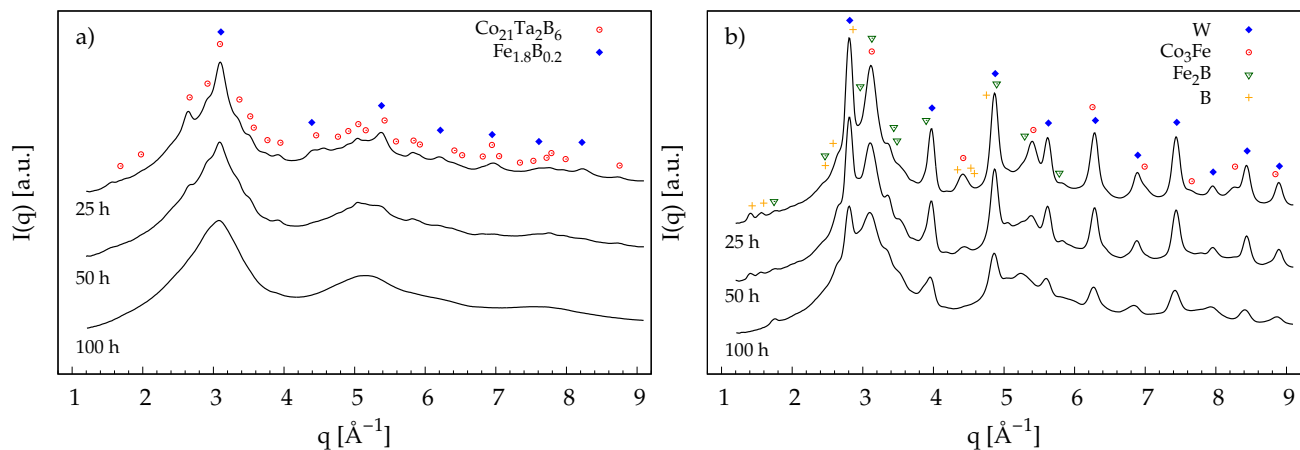

Figure 1. X-ray diffraction patterns $I(q)$ for (**a**) CoFeTaB alloy and (**b**) CoFeWB alloy after 25, 50 and 100 h of mechanical alloying. For a better clarity curves are plotted in logarithmic scale and are vertically offset. Various symbols denote positions of Bragg peaks stemming from respective crystallographic phases.

One of the reasons for the apparently higher resistance to amorphization observed in the case of the W-alloy is probably the higher hardness of W (HV = 3430 MPa) as compared to Ta (HV = 873 MPa). In order to quantitatively describe the progress of grain refinement of bcc-W, we analyzed its XRD profiles using the Williamson–Hall method [33] , which relies on the principle that the approximate formulae for size broadening β^D and strain broadening β^ε show different dependencies on the Bragg angle θ, and thus the total line broadening β can be expressed in the form

$$\beta = \beta^\varepsilon + \beta^D = 4\varepsilon \tan\theta + \frac{K\lambda}{D\cos\theta} \tag{1}$$

where K is the Scherrer constant (in our calculations, we used $K = 1$), λ is the wavelength of X-ray radiation and D is the mean (volume average) crystallite size. In order to obtain correct information about the mean crystallite size determined from peak broadening, it is necessary to correct the measured line widths β_{exp} for the instrumental contribution, as described in the experimental section. Figure 2a shows a typical Williamson–Hall plot for the W-25 sample. Only those reflections of bcc-W were included in the analysis, which are not overlapped by reflections from other phases. As shown in Figure 2a, experimental points perfectly resemble linear dependence and fitting with the Equation (1) yields values of the mean crystallite size D and microstrain ε, 16.2(9) nm and 18(1) $\times 10^{-4}$, respectively. A similar analysis was performed for samples W-50 and W-100. As can be see from Figure 1b, the mean crystallite size D of bcc-W phase tends to decrease with increased milling, whereas the lattice constant a shows the opposite behavior. The level of microstrain ε decreases with increasing milling time and values 11(1) $\times 10^{-4}$ and 2(2) $\times 10^{-4}$ are observed for the W-50 and W-100 samples, respectively. Decreasing values of ε may point to the relaxation of a microstructure induced by MA.

3.2. Transmission Electron Microscopy

Figure 3 shows the collection of HRTEM images of Ta- and W-containing alloys at various stages of mechanical alloying. Due to the larger diameter of powder particles, their transparency for electron beam was lowered and, consequently, an HRTEM phase contrast attenuated. Despite this, the HRTEM patterns were still resolved with enhancement of the contrast by applying the fast Fourier transformation filtering together with the inverse fast Fourier transformation. Both alloys revealed crystalline structures with nanocrystals with crystallite sizes well bellow 50 nm. TEM observation on samples Ta-25 and W-25 confirms that their structures are completely crystalline. This follows from a detailed comparison of different areas, showing that the W-25 sample shows, on average, larger crystallites as compared to the Ta-25. The HRTEM image of the W-25 sample (Figure 3d)

shows only two nanocrystals fully covering the captured sample area. For better clarity, the grain boundaries between different crystalls are depicted by white dashed lines. The grain boundaries were estimated in accordance with visualized atomic planes exhibited only by crystalline volume. The superposition of signals from larger nanocrystals is revealed by SAD in which diffraction rings are formed by sharp but sparse reflections (see the inset in Figure 3d). An HRTEM image of the Ta-50 sample (Figure 3b) indicates its structure consists of nanocrystals embedded in an amorphous matrix. The SAD pattern contains only a few, very weak crystalline reflections. Amorphous rings become accentuated, indicating that the amorphous phase has a dominant volume fraction. The opposite situation is seen in the case of the W-50 sample (Figure 3e), which shows a much larger fraction of the crystalline phase, with minor content of the amorphous phase. After 100 h of milling, the Ta-alloy transforms into a fully amorphous single-phase material without any indication of crystalline artifacts (Figure 3c). The corresponding SAD pattern exhibits just two halo rings, which is evidence of a completely amorphous structure. In contrast, the W-100 sample still retains its crystalline character (Figure 3f). Its structure consists of fine nanocrystals and an amorphous phase. Despite the crystalline reflections, diffraction rings visible on SAD pattern are not as clear, intense and well-defined as the rings on SAD patterns corresponding to samples W-25 and W-50. The reflections are rather scattered and not evenly distributed along diffraction rings, which is a typical effect of very fine nanocrystals.

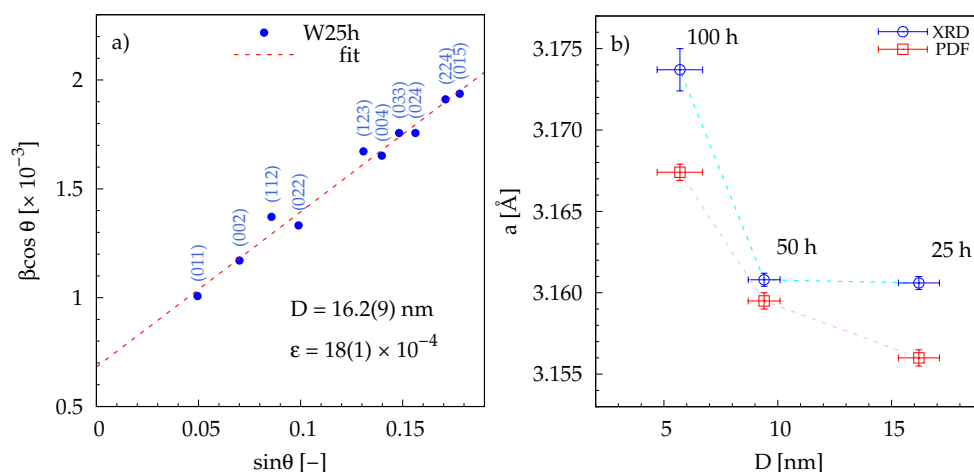

Figure 2. (**a**) Williamson–Hall plot for series of Bragg reflections belonging to the bcc-W phase in CoFeWB alloy after 25 h of mechanical alloying. The mean value of crystallite size *D* and microstrain *ε* were determined from the intercept of the regression line with *y*-axis and its slope, respectively. (**b**) Evolution of the mean crystallite size *D* and lattice parameter *a* of the bcc-W phase in CoFeWB alloy with milling time as determined by XRD and PDF (only lattice parameter) in reciprocal and real space, respectively. Dashed lines are guides for the eye.

However, the HRTEM image enables analysis of interplanar distances via fast Fourier Transformation of selected parts. The crystalline parts designated in Figure 3f as C1 to C4 were processed by filtering to obtain a higher information content. Filtered images were converted to the 2D Fourier patterns (see Figure 4). Analysis of the obtained reflections confirmed that interplanar distances belong to the (311) plane system of tetragonal B phase and (110) plane systems of bcc-W and bcc-Co$_3$Fe phases, which were also identified by XRD (see Figure 1). Although TEM analysis has a very local character, the obtained results prove a similar tendency in the microstructure evolution of both alloys, as seen by XRD, which averages the structural information over a much larger sample volume. In case of both alloys, it is seen that the crystallite size decreases with increasing milling time, which is usually observed for the MA technique [34]. Furthermore, an increase in the fraction of amorphous phase with milling time is observed.
Figure 3. High-resolution TEM images with insets showing corresponding SAD patterns of CoFeTaB (**a**–**c**) and CoFeWB (**d**–**f**) alloys at various stages of mechanical alloying: (**a**) Ta-25 specimen with fully crystalline structure, (**b**) Ta-50 specimen shows traces of few nanocrystals, (**c**) Ta-100 appears completely amorphous, (**d**) W-25 specimen appears fully crystalline, (**e**) mostly crystalline structure of the sample W-50, and (**f**) mixture of nanocrystals and amorphous structure in the sample W-100. Amorphous and crystalline areas appearing in TEM images are labeled by letters A and C, respectively.

The actual chemical compositions of powder materials after 100 h of MA were verified by EDX spectroscopy analysis using a scanning electron microscope. A very good agreement with the nominal composition was confirmed. No extra relevant elements or elements with excessive fraction were found. The determined compositions (in at.%) for the Ta-100 and W-100 are $Co(45.0)Fe(20.6)T(3.5)B(30.9)$ and $Co(49.2)Fe(22.7)W(3.1)B(25.0)$, respectively. An almost perfect match with the nominal composition in case of the Ta-100 sample can be explained by its fully amorphous nature, which is intrinsically homogeneous.

3.3. Local Atomic Structure from Pair Distribution Function

The scattering intensity profiles $I(q)$ presented in Figure 1 were corrected for background scattering, sample absorption, incoherent and multiple scattering, and then normalized with respect to the chemical composition and atomic scattering factors of respective atoms by procedures described in [22,23]. In this way, each intensity profile $I(q)$ was transformed into the structure factor $S(q)$, which represents an intrinsic property of a given material, directly related to its scattering amplitude. Figure 5 shows a comparison of q-weighted structure factors $F(q) = q[S(q) - 1]$ for both alloys at different stages of mechanical alloying. One should bear in mind that structure factors $F(q)$ qualitatively show the same structural information about the progress of mechanical alloying, as concluded from the raw scattering intensity profiles $I(q)$ presented in Section 3.1.
Figure 4. 2D Fourier transformation of the corresponding areas labeled as C1, C2, C3 and C4 in the HRTEM image of the sample W-100 presented in Figure 3f. The areas C1 and C4 were identified as tetragonal B phase. Cubic phases bcc-W and bcc-Co_3Fe were identified in areas C2 and C3, respectively. Numbers in brackets represents Miller indices of visualized atomic plane system.

Longer milling times imply the increasing extent of structural disorder present in the milled material due to various processes, such as grain refinement, the generation of structural defects and, finally, amorphization, which is taking place in both alloys, although at different rates. All of this gives rise to a diffuse scattering signal, which is spread in a wide range of reciprocal space. Such a signal carries essential information regarding the local atomic ordering and can be better analyzed when Fourier transforming structural information is represented in reciprocal space by structure factor $F(q)$ to a reduced pair distribution function $G(r)$, which represents the same structural data, but in real space. The corresponding reduced pair distribution function, $G(r)$, can be obtained through a sine FT

$$G(r) = 4\pi r[\rho(r) - \rho_0] = 4\pi r \rho_0[g(r) - 1] = \frac{2}{\pi} \int_0^\infty q[S(q) - 1]\sin(qr)dq \qquad (2)$$

where $\rho(r)$ and ρ_0 are the atomic pair density and average atomic number density, respectively, $g(r) = \rho(r)/\rho_0$ is the pair distribution function, and r is the radial distance. As can be seen from Equation (2), a reliable $G(r)$ can be obtained when $S(q)$ is measured up to high magnitudes of wave momentum vector transfer q. In this study, we used $q_{max} = 18\,\text{Å}^{-1}$. It should be noted here that the q_{max} is closely related to the real space resolution Δr. Choosing a q_{max} which is too low implies the presence of spurious oscillations, due to the so-called truncation error, which can be readily seen on a low r-range of $G(r)$ [35]. On the other hand, pushing the q_{max} to a higher values causes the worsening of Δq resolution, which is manifested by a dampening of $G(r)$'s oscillations at larger r-values, and thus sets the upper limit for the correlation length, which can reliably be observed [35].

Figure 5. Room temperature q-weighted total structure factors $F(q)$ for (**a**) CoFeTaB alloy and (**b**) CoFeWB alloy after 25, 50 and 100 h of mechanical alloying. For better clarity, curves are vertically offset.

Figure 6 shows a comparison of the total reduced-pair distribution functions $G(r)$ obtained through a sine Fourier transform of structure factors $F(q)$ presented in Figure 5. In case of the Ta-alloy (Figure 6a), it is readily seen from $G(r)$ that, after 100 h of mechanical alloying, a fully amorphous material is formed. Its $G(r)$ reveals the presence of broad oscillations which rapidly decay with increasing r-values and are not visible above 16 Å. This is a fingerprint of the missing long-range order, usually observed in materials with a high degree of structural disorder, such as metallic glasses [23]. As can be seen from Figure 6b, $G(r)$ of the W-25 sample shows much sharper peaks as compared to the Ta-25. Apparently, the presence of W hinders the destabilization of its structure due to mechanical alloying and preserves long-range order, as manifested by well-resolved oscillations, visible up to large r-values. $G(r)$ oscillations are getting broader and less intense with the increase in milling time. This is a direct consequence of gradual increase in structural disorder induced by mechanical alloying. Nevertheless, 100 h of milling is not sufficient to reach the fully amorphous state of the W-alloy, as evidenced by relatively strong oscillations in the final $G(r)$. Dampening of the $G(r)$'s oscillations at large r values (seen in Figure 6b) is a consequence of the limited Δq resolution in reciprocal space [35]. Evaluation of $G(r)$ for standard material LaB_6 (not shown here) indicates that the Δq resolution (influenced by our setting with q_{max} = 18 Å^{-1}) restricts the maximum correlation length to 105 Å. Inspecting the tails of $G(r)$s above 50 Å (Figure 6b) indicates that the oscillations in the sample W-100 enter the noise level at the maximum correlation length r = 65(5) Å. This distance basically represents the mean crystallite size associated with the bcc-W phase and is in perfect agreement with the value 57(10) Å obtained by XRD (see Figure 1). In case of samples W-25 and W-50, the mean crystallite sizes cannot be determined in such a way since their $G(r)$s suffer from limited Δq resolution.

Figure 6. Room-temperature total pair distribution functions $G(r)$ for (**a**) CoFeTaB and (**b**) CoFeWB samples after 25, 50 and 100 h of mechanical alloying. The mean atomic number density ρ_0 was determined by a linear fit of $G(r)$'s low r part (where $r \leq 1.8$ Å) to $-4\pi r \rho_0$ (depicted by solid orange lines). For better clarity, curves are vertically offset. In case of CoFeWB sample, corresponding $G(r)$s were fitted on r-range $\langle 9, 29 \rangle$ Å. Fitting and difference curves are depicted by solid red and green lines, respectively. The tails above 50 Å are magnified by a factor 50 (for W-25 and W-50) and 100 (for W-100). Small arrow located at r = 65 Å indicates a distance at which signal enters a noise level, depicted by two parallel dashed lines.

To quantitatively describe the impact of MA on a medium-range order (r-range $\langle 9, 29 \rangle$ Å) of W-containing samples, its $G(r)$s were fitted using the program PDFgui [27]. The structural model consisted of the most prominent crystalline phases, bcc-W and bcc-Co_3B. As can be seen from Figure 6b, the proposed model satisfactorily describes features of $G(r)$. It follows from fitting results that, in case of bcc-W phase, its lattice parameter increases from 3.1560(5) Å at 25 h up to 3.1674(5) Å at 100 h. Similarly, the lattice parameter of bcc-Co_3B phase increases from 2.8498(3) Å at 25 h up to 2.8797(4) Å at 100 h. As can be seen from the comparison in Figure 1, there is a slight offset between the values obtained by the XRD and PDF methods, although both reveal similar trends for the lattice parameter change with milling time. The mean square displacement $\langle u^2 \rangle$ of the atomic positions gives

a direct measure of the atomic disorder. Refined values of the $\langle u^2 \rangle$ parameter associated with bcc-W and bcc-Co$_3$B phases after 25 h of MA are 0.0101(1) Å^2 and 0.0961(2) Å^2, respectively, and after 100 h of milling change to 0.0046(1) Å^2 and 0.0962(6) Å^2, respectively. One may conclude that the bcc-Co$_3$B phase shows a value one order of magnitude higher than the $\langle u^2 \rangle$ parameter as compared to bcc-W phase and this remains constant for milling times above 25 h. The observed decrease in the $\langle u^2 \rangle$ in case of bcc-W may be correlated with decreasing values of microstrain ε, as revealed by Williamson–Hall analysis.

Figure 7 shows a detailed view of $G(r)$, depicting the first coordination shell (the nearest atomic neighborhood covering r-range 1.8–3.4 Å) for Ta- and W-containing alloys after different milling times. It is worth noting that the peak position in $G(r)$, its width and area are closely related to the bond length, distribution of bond lengths and coordination number, respectively. Table 1 lists all atomic pairs together with their bond lengths r_{ij} (calculated as a sum of atomic covalent radii), X-ray weighting factors w_{ij} and enthalpies of mixing [36]. Depending on the concentration c_i and X-ray atomic scattering factors $f_i(q)$ of constituent elements, respective atomic pairs contribute with different weights w_{ij} to the total $S(q)$ and $G(r)$. As can be seen from Figure 7a, the first coordination shell of the fully amorphous Ta-100 shows a broad main peak located at 2.6 Å with a small pre-peak at 2.05 Å and right shoulder at 2.9 Å, which are mainly due to the bond lengths of atomic pairs (Co,Fe)–(Co,Fe), (Co,Fe)–B and Ta–Ta, respectively. In case of the W-100, there is also a good agreement between theoretically expected bond lengths and the shape of the first coordination shell. In addition to the amorphous phase, there are visible traces of bcc-W (with lattice parameter a = 3.174 Å), which still contributes to the first shell by two characteristic peaks, stemming from the inter-atomic distances between W atoms in bcc structure, located at $a\sqrt{3}/2$ (2.74 Å) and a (3.17 Å).

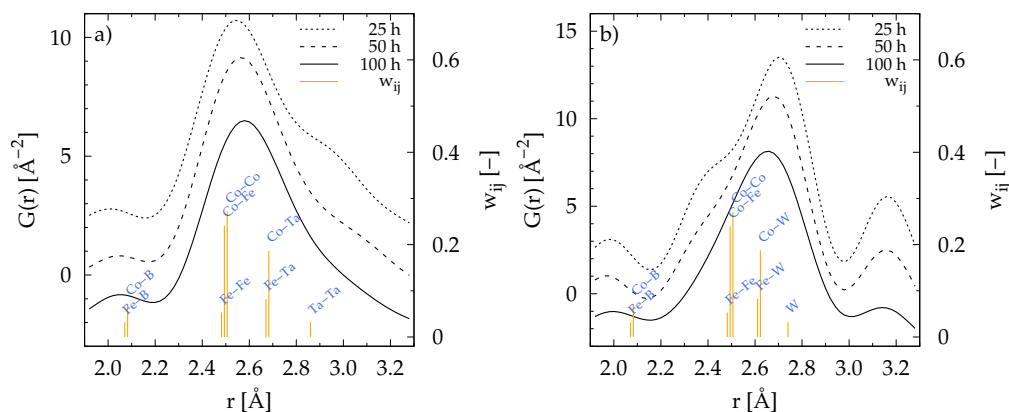

Figure 7. Detailed view of the first coordination sphere, as seen from the total pair distribution function $G(r)$ for (**a**) CoFeTaB alloy and (**b**) CoFeWB alloy after 25, 50 and 100 h of mechanical alloying. For a better clarity, curves are vertically offset. Positions and heights of the vertical lines denote bond lengths r_{ij} of atomic pairs and X-ray weighting factors w_{ij}, respectively.

Since $\rho(r)$ becomes zero below a certain r_{min}, the average atomic number density ρ_0 can be easily obtained by a linear fit of $G(r)$'s low r part (where $r \leq r_{min}$) to $-4\pi r\rho_0$. From $G(r)$ the radial distribution function, $RDF(r)$, can be calculated by

$$RDF(r) = 4\pi r^2 \rho_0 g(r) = 4\pi r^2 \rho_0 + rG(r). \tag{3}$$

The average total coordination number, CN, around any given atom in a spherical shell between radii r_1 and r_2, can be calculated as

$$CN = \int_{r_1}^{r_2} RDF(r)\,dr = \frac{4\pi\rho_0}{3}\left(r_2^3 - r_1^3\right) + \int_{r_1}^{r_2} rG(r)\,dr. \tag{4}$$

Fitting $-4\pi\rho_0 r$ to the $G(r)$ for $r \leq 1.8\,\text{Å}$ the value of the mean atomic density ρ_0 was determined. The average total coordination number CN in the first coordination shell (between radii 1.8 and 3.4 Å) was calculated according to Equation (4). It follows from the numerical data presented in the Table 2 that the mean atomic density ρ_0 and total coordination number CN for both alloys decrease with increasing milling time. Furthermore, the data suggest that the relative change in ρ_0 and CN with milling time is larger in case of the W-alloy. However, one should bear in mind that the Ta-alloy is after 25 h of MA, much closer to its final amorphous state, and thus reveals slower dynamics with increasing milling. CoFeTaB amorphous alloy is known to exhibit rather dense atomic packing [37]. For example, the work of Kaban et al. [37] reports partial coordination numbers, which, after adjusting for the alloy composition, yield the total coordination number 13 ± 1, in perfect agreement with our study, i.e., 14.2 ± 0.3 for fully amorphous Ta-100.

Table 1. Bond lengths r_{ij}, X-ray weighting factors w_{ij} and enthalpy of mixing ΔH_{mix} [36] of atomic pairs in Ta- and W-containing alloys. Bond lengths r_{ij} of atomic pairs were calculated as a sum of nominal atomic covalent radii. Weighting factors w_{ij} were calculated for $q = 0\,\text{Å}^{-1}$ using Equation $w_{ij}(q) = [(2 - \delta_{ij})c_i c_j f_i(q) f_j(q)]/[\sum_{i=1}^{n} c_i f_i(q)]^2$, where δ_{ij} is the Kronecker delta function ($\delta_{ij} = 1$ for $i = j$ and $\delta_{ij} = 0$ for $i \neq j$), c_i and $f_i(q)$ are the atomic concentration and atomic scattering factor [25] of the atomic species of type i (i = Co, Fe, Ta/W, B), respectively.

3.4. X-ray Absorption Spectroscopy

Experimentally recorded absorption scans $\mu(E)$ were converted to the $\chi(k)$ functions by $\chi(k) = [\mu(E) - \mu_0(E)]/\Delta\mu_0$ in which $\mu_0(E)$ is a smooth background function representing the absorption of an isolated atom, $\Delta\mu_0$ is the measured jump in the absorption $\mu(E)$ at the respective absorption edge energy E_0. The $\chi(k)$ represents oscillations as a function of photo-electron wave number k and is further referred to as the EXAFS signal. Various frequencies apparent in the EXAFS signal are due to the different neighboring coordination shells, which can be described by the following equation

$$\chi(k) = \sum_j \frac{N_j}{kR_j^2} S_0^2 F_j(k) \exp(-2k^2\langle u_j^2\rangle) \sin[2kR_j + \delta_j(k)] \tag{5}$$

where the summation goes over different coordination shells j, $F_j(k)$ and $\delta_j(k)$ are the scattering amplitude and phase shift in the atoms neighboring the central excited atom, respectively, N_j is the number of neighboring atoms (partial coordination number) which are at a distance R_i from the excited atom, $\langle u_j^2\rangle$ is the mean square displacement of the neighboring atoms and gives a direct measure of the atomic disorder, S_0^2 is the energy-independent, many-body amplitude reduction factor that accounts for losses only within the central absorbing atom and is independent of the chemical nature and type of back-scattering atoms. In EXAFS, since one selects the absorbing center, the measured signal signal is summed over the subset of all the atomic species around the absorbing atom. This means that EXAFS is highly sensitive to the nearest-neighbor atomic environment surrounding the absorbing atom, which is often a crucial point in the characterization of structural disorder [38].

EXAFS signals $k^2\chi(k)$ of Ta- and W-containing alloys recorded above Fe-K, Co-K, Ta-L_3 and W-L_3 edges are shown in Figures 8a–c and 9a–c, respectively. It is evident that all EXAFS signals extend to a maximum of k at around $12\,\text{Å}^{-1}$. This is closely related to the loss of structural order during the MA process. The only exception is EXAFS signals of W-containing samples, measured above the W-L_3 edge, which show strong and well-resolved oscillations visible up to $15\,\text{Å}^{-1}$. The corresponding phase-corrected magnitudes $|FT(k^2\chi(k))|$ for the Ta- and W-containing alloys are shown in Figures 8d–f and 9d–f. After 25 h of MA, similarity with a bcc-Fe-like structure can be observed for both alloys. Further milling implies a loss of structural order, as manifested by washing out of the second coordination shell signal, and only the peak associated with the first coordination sphere is visible. The local atomic environments, as seen from the perspective of Fe and Co atoms, are quite similar for both alloys and exhibit a broad peak located between 1.5 and 3 Å. EXAFS signal above Ta-L_3 edge show a similar behavior. All of this gives a direct proof of the excellent intermixing of Co, Fe, Ta and B atoms in Ta-alloy, and is in agreement with the XRD and TEM observations, confirming its fully amorphous structure after 100 h of MA. On the other hand, sharp and strong EXFAS signals measured above the W-L_3 edge for the W-containing samples (Figure 9f) give direct evidence of the poor miscibility of W among Co, Fe, B atoms, and their similarity with a reference W foil signal confirms that W atoms rather prefer the configuration of a stable bcc-W phase. EXAFS measurements confirm that MA of the CoFeWB alloy results in the formation of a two-phase material consisting of amorphous Co-Fe-B and nanocrystalline bcc-W. The main reasons behind such a poor miscibility of W within Co-Fe-B system are larger values of hardness, elastic, shear and bulk modulus and, most importantly, a much lower extent of enthalpy mixing with Co, Fe and B (see Table 1) compared with Ta.

To quantitatively compare the experimentally obtained EXAFS signals presented in Figures 8 and 9, they were fitted using the so-called quick first shell model. As for the model definition, we propose that the central absorbing atom is surrounded by Co and B atoms only, which are mostly abundant in both alloys. As the Co and Fe atoms have similar radii and scattering powers, it is reasonable to consider only Co atoms. This assumption makes the model simple, physically justified and, at the same time, robust for the fitting. According to Equation (5), for each atom, the j surrounding the central absorbing atom has four parameters which can be refined, i.e., coordination number, N_j, distance from the central atom, R_j, energy shift, ΔE_{0j}, and mean square atomic displacement factor $\langle u_j^2\rangle$. Altogether, eight parameters are needed to describe this model. Since experimental data have limited Δk range, it is necessary to reduce the number of parameters so that a reliable fit is obtained. Therefore, the following constraints were imposed on our model: (i) $\Delta E_{0,Co} = \Delta E_{0,B}$, (ii) $\langle u_{Co}^2\rangle = \langle u_B^2\rangle$ and (iii) $N_{Co} + N_B = CN$, as determined from X-ray-

scattering experiments (see Table 2). In this way, the number of fitting parameters can be reduced to five, which is just below the limit set by the Δk and Δr ranges used in fitting.

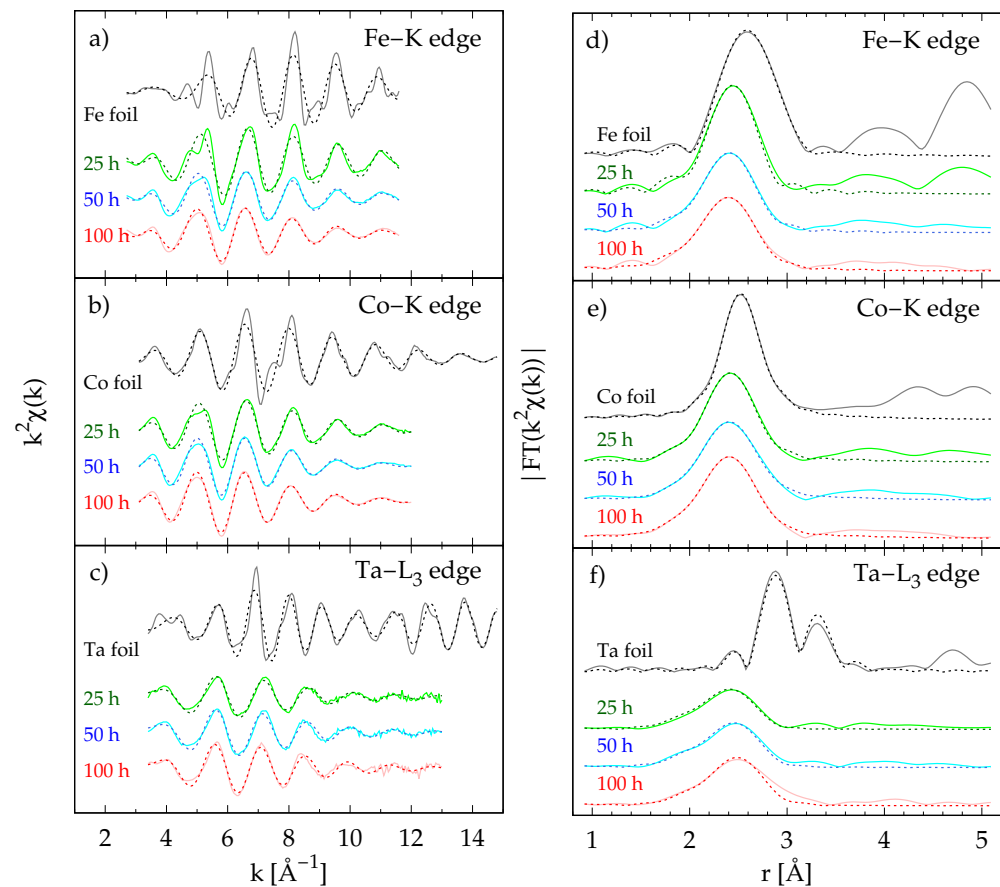

Figure 8. EXAFS signals $k^2\chi(k)$ in k-space (**a**–**c**) and corresponding magnitudes of its Fourier transforms in r-space (**d**–**f**) as measured above Fe-K, Co-K and Ta-L_3 edges for the alloy CoFeTaB after 25, 50 and 100 h of mechanical alloying. The solid lines correspond to experimental data, whereas dashed lines correspond to fitting curves based on the quick first shell model. Additionally, signals from reference foils are presented. For better clarity, curves are vertically offset.

EXAFS data were fitted to the proposed model using following settings for the k and r ranges: (a) Fe-K edge, $k = \langle 2.7, 11.5 \rangle$ Å^{-1}, $r = \langle 1.3, 2.6 \rangle$ Å , (b) Co-K edge, $k = \langle 3.1, 12 \rangle$ Å^{-1}, $r = \langle 1.3, 2.6 \rangle$ Å , (c) Ta-L_3 edge, $k = \langle 3.4, 13 \rangle$ Å^{-1}, $r = \langle 1.2, 3.0 \rangle$ Å and (c) W-L_3 edge, $k = \langle 3.1, 14.7 \rangle$ Å^{-1}, $r = \langle 1.6, 3.4 \rangle$ Å . The value of parameter S_0^2 at a given absorption edge was obtained by fitting the EXAFS signal of a corresponding reference foil based on its crystal structure (bcc-Fe, fcc-Co, bcc-W and bcc-W). It should be noted here that, for fitting the EXAFS data at W-L_3 edge, we used two single scattering paths with lengths 2.74 Å and 3.17 Å as suggested by the structural model of bcc-W. As can be seen from data presented in Figures 8 and 9, the proposed models satisfactorily describe the observed features of EXAFS signals. Numerical results from fitting the first coordination shell are presented in Tables 3 and 4. In case of the Ta-alloy, it is readily seen that the high degree of structural disorder among all its constituents is evidenced by the relatively large values of their mean atomic displacement factors $\langle u^2 \rangle$. In case of the W-alloy, one can observe slower amorphization dynamics. Its local atomic structure, as seen from the perspective of Fe and Co atoms, resembles similar features to the Ta-alloy. The mean atomic displacement factors $\langle u^2 \rangle$ associated with Co, Fe and B atoms gradually increase during MA and, after 100 h, reach similar values to the Ta-alloy. This indicates the formation of an amorphous Co-Fe-B phase in the W-alloy. As can be seen from Figure 9f, W atoms do not intermix with other alloy constituents and prefer the bcc-W phase (see refined values in Table 4). An apparent

discrepancy between the values of the $\langle u^2 \rangle$ parameter, obtained by a fitting medium range order of $G(r)$ (see Section 3.3) and by fitting EXAFS data based on the first coordination shell (see Table 4), is seen in case of bcc-W phase. However, such a difference is due to the completely different length scales, to which both approaches are sensitive.

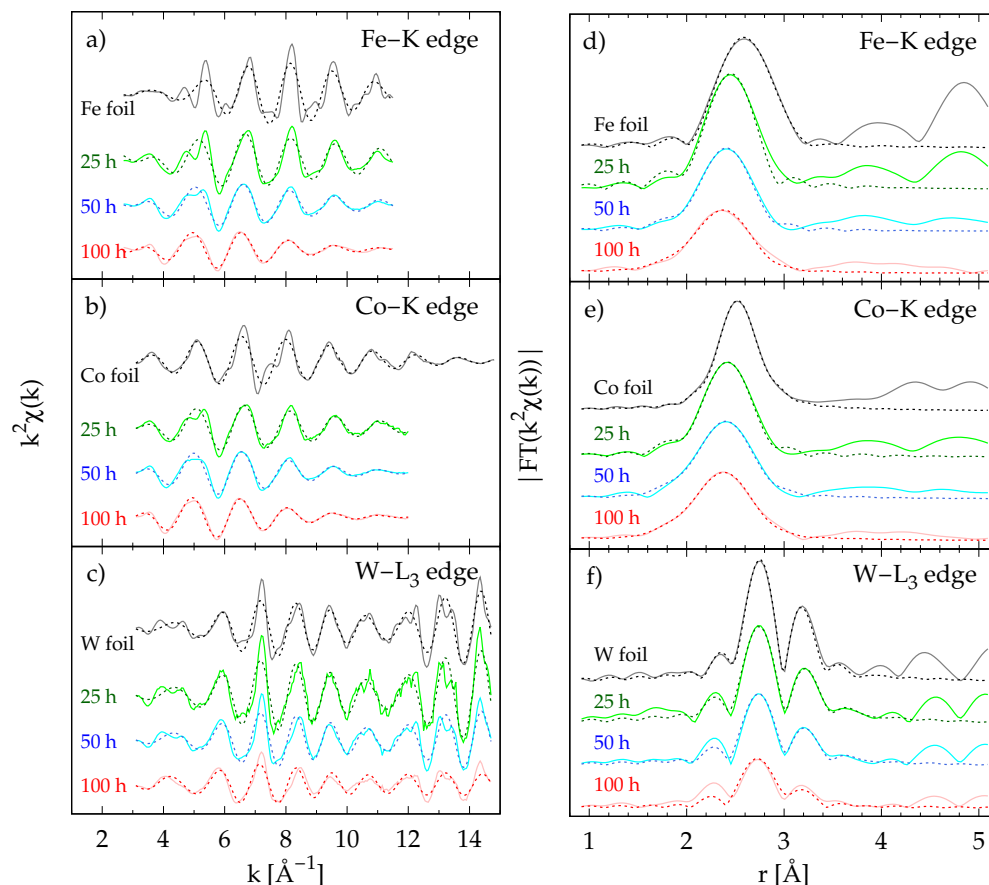

Figure 9. EXAFS signals $k^2\chi(k)$ in k-space (**a**–**c**) and corresponding magnitudes of its Fourier transforms in r-space (**d**–**f**) as measured above Fe-K, Co-K and W-L$_3$ edges for the alloy CoFeWB after 25, 50 and 100 h of mechanical alloying. Solid lines correspond to experimental data, whereas dashed lines correspond to fitting curves based on the quick first shell model. Additionally, signals from reference foils are presented. For better clarity, curves are vertically offset.

3.5. Magnetic Properties

Figure 10 shows the room-temperature hysteresis loop of CoFeTaB and CoFeWB alloys after 100 h of MA. Comparing both hysteresis loops, it follows that the W-100 shows larger values of saturation magnetization and coercivity as compared to the Ta-100.

The saturation values of specific magnetization σ_s for the Ta-100 and W-100 are 96.4 and 109.8 Am^2/kg, respectively. It could be presumed that the higher magnetization in case of the W-100 is primarily due to iron contamination from milling media. Therefore, let us calculate what the iron fraction x_{Fe} should be according to that assumption. Inserting the values of the saturation magnetization of iron ($\sigma_{Fe} = 222$ Am^2/kg) of the Ta-100 ($\sigma_{Ta} = 96.4$ Am^2/kg), and of the observed increase in the saturation magnetization ($\Delta\sigma = \sigma_W - \sigma_{Ta} = 13.4$ Am^2/kg) into the equation $\Delta\sigma = x_{Fe}\sigma_{Fe} - x_{Fe}\sigma_{Ta}$, we obtain a relatively high value for the iron fraction $x_{Fe} = 10.7$ wt.%. However, such a high amount of iron could be better resolved by XRD. Taking the type of mill, speed, and duration of milling into account, such a high value of x_{Fe} could not be explained in terms of contamination by attrition. It was reported by many works that the magnitude of iron contamination of the powders milled with the steel grinding medium is in the range of 1–4 wt.% [16]. The most probable explanation for the higher magnetization in case of the W-100 is the fact that W stays in bcc-W phase and does not dilute the net magnetization of amorphous Co-Fe-B by dissolving in it, as Ta does.
Figure 10. Room temperature hysteresis loop of (**a**) CoFeTaB and (**b**) CoFeWB alloys after 100 h of milling traced in a magnetic field with maximum induction of μ_0H = 1.8 T. The insets show detailed view of hysteresis loop origin. The width of the loop is depicted with the red dashed line and corresponds to coercivity by relationship $2\mu_0 H_c$.

Values of coercivity H_c for the Ta-100 and W-100 are 8.75 kA/m ($\mu_0 H_c$ = 11 mT) and 12.73 kA/m ($\mu_0 H_c$ = 16 mT), respectively. The relatively large values of H_c for both materials are mainly due to the pinning of the domain walls by stress sources, intrinsic fluctuations in material properties and particle surface irregularities [39]. A significantly larger va,lue of H_c for the W-100 is due to its microstructure consisting of amorphous-phase and nanocrystalline bcc-W, which acts as an effective pinning center for the domain wall motion [40].

Figure 11 shows the temperature dependence of magnetization $\sigma(T)$ for the Ta-100 and W-100. In both samples, the initial decrease in magnetization with temperature is caused by the decrease in the magnetization of the amorphous phase as it approaches its Curie point T_C, where the paramagnetic state is reached. The Curie temperature was determined from the inflection point using the derivative of magnetization with respect to temperature, i.e., $d\sigma/dT$. The Ta-100 shows the Curie temperature of the amorphous phase T_C = 695(5) K. In case of the W-100, there are two transitions detected with Curie temperatures 700(5) K and 780(5) K. This may point to the inhomogeneities of an amorphous phase [41]. After reaching T_C, the magnetization of the powder samples does not drop to zero and eventually increases due to the thermally activated structural changes (relaxation, crystallization) occurring at higher temperatures.

Figure 11. Temperature dependence of magnetization $\sigma(T)$ for (**a**) CoFeTaB and (**b**) CoFeWB alloys after 100 h of milling. Dashed lines show the respective temperature derivative of magnetization, $d\sigma/dT$. Vertical arrows depict the possible magnetic transition with corresponding Curie temperatures.

4. Conclusions

Our results have shown that wet mechanical alloying, using hexane as a process control agent, represents an effective way of preparing materials with a high degree of structural disorder. A wet MA of $Co_{43}Fe_{20}Ta_{5.5}B_{31.5}$ powder mixture for 100 h of milling results in the formation of a fully amorphous material. Mechanically induced amorphization occurs through the formation of intermediate phases of $Co_{21}Ta_2B_6$ and $Fe_{1.8}B_{0.2}$. It has been shown that substituting Ta with W effectively suppresses GFA. After 100 h of MA of $Co_{43}Fe_{20}W_{5.5}B_{31.5}$ powder mixture, a nanocomposite material consisting of an amorphous Co-Fe-B phase and nanocrystalline bcc-W was synthesized. The main reasons for the poor miscibility of W within the Co-Fe-B system are larger values of hardness, elastic, shear and bulk modulus and, most importantly, a much lower extent of enthalpy of mixing with Co, Fe and B as compared with Ta. The observation of the local atomic structure by means of pair distribution function and extended X-ray absorption fine-structure spectroscopy were used to characterize the local atomic structure at various stages of MA. Based on observed changes in the first coordination sphere, it can be concluded that MA significantly alters the short-range order of both alloys.
