*) For each allele of each strain the presence or absence in the other 79 strains was quantified. Each correspondence between the allele of the index strain and that of one of the other strains was normalized with respect to the number of strains comprising the subject strain's clade as defined in figure 1, in order to account for over-, or under-sampling of the different clades. Since 13 groups are defined (9 large clades and 4 one- or two-strain groups), the maximum possible value is 13; the average value was 4.5. Values less than 5% of the average are highlighted in bold print. Strains are presented in the order of clades defined in figure 1.
