Abstract: The aim of this study is to evaluate factors associated with long-term peri-implant bone-loss and to create a statistical model explaining bone-loss. The dental records in a private periodontal practice were screened for implant-patients with a minimal follow-up period of 8 years with periapical radiographs at implant-placement (T0) and last follow-up (Tf). Collected data included demographics, general health, medications, periodontal parameters, implant parameters, bone augmentation procedures, restoration and antagonist data, number of supportive periodontal appointments (SPT), and radiographic bone-loss between T0 and Tf. Bivariate and Mixed Logistic Regression analyses were performed. “Goodness-of-fit” of the model was elaborated with Receiver Operating Characteristic Curve (ROC) analyses. Thirty-seven patients receiving 142 implants were included. Mean clinical follow-up period was 11.7 ± 3.7 years (range 8–23). Most implants 64.4% were SPT-maintained more than twice a year. Patients with osteoporosis and smokers were prone to increased radiographic peri-implant bone-loss. External-hex implants placed without guided bone regeneration (GBR) and implants 10–12 mm long and diameter of 3.7–4 mm showed less peri-implant bone-loss. The model’s Area Under the Curve (AUC) was 76.9% (Standard Error 4.6%, CI 67.8–86%).

Keywords: long-term follow-up; dental implant; marginal bone loss; periodontal private practice

1. Introduction

Installation of dental implants for fixed or removable rehabilitation has become a common practice in the last decades [1,2], and its high rates of survival and success are well documented [3,4]. It is currently accepted that implants go through periods of physiological remodeling after implant placement and after completion of implant-supported prosthesis, after which comes a period of steady state [5]. Periapical radiographs are the standard imaging tool to monitor peri-implant bone level, which manifests itself as physiological remodeling of crestal bone loss varying between 0.5 and 2 mm from implant installation to initial loading [6,7] followed by a steady state when the average annual decrease in peri-implant bone level is less than 0.1 mm/year [8]. The average measurement error of radiographic bone loss is defined as 0.5 mm [9]. Therefore, if no significant bone loss occurs during the steady state period, implants should be followed for at least 5 years before significant bone loss exceeds measurement error. The current classification of an implant with peri-implantitis in the absence of a radiograph after initial healing/loading comprises bone loss ≥ 3 mm apical of the most coronal portion of the intra-osseous part of the implant together with probing pocket depth of ≥ 6 mm and bleeding on probing [9]. This definition takes into account the initial physiological remodeling as well as bone loss during the ensuing period.

Cases from “everyday practices” may enhance our understanding regarding the effectiveness of implant therapy. The evidence in implant therapy comes from private practices [10–13] and from patients treated in university clinics [3,10,14], yet more private practice data would be valuable.

We looked for patients in a single private practice who received dental implants and had documentation at least 8 years following implant installation. The main objective of the present study was to evaluate factors that were associated with long term peri-implant bone loss. Additional aim was to create a statistical model that may explain radiographic bone changes around dental implants.

2. Materials and Methods

The present retrospective observational study is based on data collected from clinical patients' files in one private practice. The study was approved by the Rambam Health Care Campus review board (0298-19-RMB). The dental records of patients attending a private periodontal practice who received dental implants as a part of their periodontal treatment or as a stand-alone procedure were screened. Periodontal and implant therapy throughout the entire study period were performed by the same periodontist (JH). The restorative therapy was provided by referring clinicians. The clinic's patient database was screened for patients who had clinical periodontal data from the time of implant installation (T0) and from at least 8 years later (Tf). This cohort was further screened for patients who had orthoradial radiographs from T0 and from Tf for measuring the distance between implant shoulder and the most coronal bone level (Figure 1). The final database consisted of patients who had both clinical and radiographic data of appropriate diagnostic quality. No other inclusion/exclusion criteria were used for patient selection. Generally, patients received periodontal active therapy that consisted of cause-related therapy, including oral hygiene instructions and motivation, scaling and root surface debridement, and surgical therapy as necessary. Patients that were additionally diagnosed with caries, defective restorations, and/or endodontal conditions were referred back to their referring dentist for dental treatment. After completion of this phase, implants were planned and installed. Some cases also required bone augmentation procedures. Patients also entered the supportive periodontal therapy (SPT) phase (the standard recommendation consisting of oral screening, oral hygiene motivation, scaling, and root and implant surface decontamination using ultrasonic and hand instruments every 3 months).

Figure 1. A periapical radiograph at the implant site, at implant placement date T0 and at the last follow-up visit Tf. (a) Intraoral periapical radiograph of three implants replacing left mandibular premolar and first and second molars at T0. The drawn lines and arrows do not show any mesial and distal distance between implant shoulder and the bone crest (no bone resorption is observed). (b) Intraoral periapical radiograph of the same implants at Tf, 8 years later. The drawn lines depict mesial and distal distance between implant shoulder and the bone crest (1.3 mm; 1.5 mm, 1.4 mm; 2.6 mm, 1.0 mm; 1.3 mm, respectively mesial and distal from the second premolar to the second molar).

For the present study, the following data were collected from patients' files.

2.1. General Data

Gender, age, general health status (presence of diabetes mellitus, cardiovascular disease, osteoporosis) medications associated with gingival side effects: calcium channel blockers (CaCB), phenytoin, cyclosporine [15–17], and smoking status (smoker/non-smoker).

2.2. Dental Data

Number of teeth and implants present in mouth, number of sites with periodontal pockets 5 mm or deeper, and full mouth bleeding score and plaque index (FMBS and PII, respectively) [18,19] at T0 and Tf. Number of SPT appointments performed between T0 and Tf.

2.3. Implant Data

- I. Brand, length, and diameter; connection type (internal hex or external hex) of implants that were installed at T0; installation timing (immediate, early (up to 8 weeks after tooth extraction), late (healed ridge)); bone augmentation data: guided bone regeneration (GBR)—yes/no, sinus floor augmentation—yes/no. If yes, lateral window or trans-crestal approach; implant explantation—yes/no, if yes, date of explanation.
- II. At Tf: Probing depth at deepest site, bleeding on probing (BOP)—yes/no, plaque on supra-structure—yes/no.
- III. Restoration (supra-structure): timing of restoration—late/immediate; restoration type—removable, fixed single, fixed multiple; restoration quality—proper, overhanging margins, and ill-fitting margins (gap).
- IV. Antagonist—absence of antagonist, teeth (intact or with filling material), tooth borne restoration (fixed/removable), and implant restoration (fixed/removable).

2.4. Radiographic Data

- I. Mesial and distal bone level were measured at T0 and Tf. (Figures 1a and 1b, respectively). Radiographs were analyzed using a computer program (VixWin ProVrs. 1.5e Gendex Dental Systems. KAVO DENTAL 200 S Kraemer Blvd, Building E2 Brea, CA 92821, USA). Analogue radiographs were digitalized with a flatbed scanner (Epson Expression 1680pro; Seiko Epson Corp.) with 600 dpi resolution and eight-bit grey values. The image files were stored as TIFF files and analyzed using the computer program VixWin on a 24" flat screen (Philips 243V5Q, 1920 × 1080; Philips) in a particular room under exclusion of natural or artificial light except the screen. After calibration using the implant's diameter, mesial and distal distances between implant shoulder and bone crest were measured using the ruler measurement tool. The degree of accuracy was 0.05 mm. A single trained and calibrated investigator (MS) performed the evaluation of all radiographs. Replicate measurements were done on 23 implants.
- II. Radiographic bone level change (the differences in radiographic bone level between Tf and T0 were calculated separately for mesial and distal of each implant. The larger of them was chosen for further calculation of mean implant bone loss).
- III. For the construction of a model of factors associated with peri-implant radiographic bone loss a new variable, "excess bone loss" was defined, consisting of peri-implant bone loss over the first year, of 1.5 mm, and the subsequent loss per year of 0.1 mm. The threshold for each implant was therefore calculated as $1.5 \text{ mm} + 0.1 * (Tf - T0) \text{ years}$. Implants were categorized as 1 if the threshold was exceeded and 0 otherwise. With this variable, logistic regression was performed.

3. Statistical Analysis

Data were tabulated in a computerized database (Microsoft Office Excel Version 16.0, Microsoft Corporation, Redmond, WA, USA). Statistical analysis was performed using Statistics Products Solutions Services (SPSS) 25.0 software for Windows (IBM North America, New York, NY, USA). Statistical data are presented as mean $\pm$ standard deviation (mean $\pm$ SD).

Two-tailed *p*-values of 0.05 or less were considered statistically significant. Data from T0 and Tf and changes that occurred during follow-up were analyzed.

- Bivariate analyses of factors influencing implant bone loss were performed using logistic regression for the calculation of the odds ratio (OR) with 95% confidence intervals (CI) and *p*-values.
- Mixed logistic regression analysis was performed to construct a model for assessment of the relation between general data, dental, and implant data. All variables with a *p*-value < 0.2 in bivariate analyses were selected as candidates for the multivariate analysis [20].
- “Goodness-of-fit” of the model was elaborated with receiver operating characteristic (ROC) analyses. ROC analysis provides tools to select possibly optimal models and to discard suboptimal ones independently from (and prior to specifying) the cost context or the class distribution. ROC analysis is related in a direct and natural way to cost/benefit analysis of diagnostic decision making. ROC is a probability curve and the Area Under the Curve (AUC) represents degree or measure of separability. It tells how much a model is capable of distinguishing between classes. In the present study, the higher the AUC, the better the model explains the association between parameters and peri-implant bone loss. Values over 70% indicate a good fit of the model [21].

4. Results

4.1. General Data

A total of 219 patients fulfilled the initial clinical ≥ 8 -years follow-up criterion. Of those, 37 patients were identified as also having orthoradial radiographs of the implants of adequate diagnostic quality. This cohort of patients received 142 implants. Four implants were lost during the follow-up period. Before implant installation, 35 patients (95%) were diagnosed as periodontitis patients [22] (formerly, chronic periodontitis) [23] and the rest were gingivitis patients. The mean follow-up period was 11.7 ± 3.7 years (range 8–23, median 10.5 years). Male/female ratio was 41%/59% (15/22). Mean age at implant placement was 55 ± 7.6 years (range 34.7–74.), and no patients reported taking calcium channel blockers, phenytoin, or cyclosporin. Six patients (16%) took anticoagulant medications. Thirteen patients (53%) reported having cardiovascular diseases. Diabetes and osteoporosis were reported by 4 (11%) and 2 patients (5%), respectively. Eight patients (22%) were smokers (Table 1).

Table 1. General data.

Characteristics	% (n)
Age (years)	55 ± 7.6 (34.7–74)
Gender (male/female)	16% (6)/41% (15)/59% (22)
Smoking (no/yes)	78% (29)/22% (8)
Systemic Diabetes/CVD/Osteoporosis	11% (4)/53% (13)/5% (2)
CaCB/Phenytoin/Cyclosporin	0
Anticoagulants	16% (6)

4.2. Dental Data

The mean number of teeth at T0 was 21.8 ± 4.2 (range 10–29), and the number of pre-existing implants was 1 ± 1.5 (range 0–5). Number of sites with PD ≥ 5 mm was 6.7 ± 8.5 (range 0–40). FMBS and

PII at T0 were $19.5\% \pm 15.4\%$ (1%–80%) and 1.1 ± 0.4 (0.3–2), respectively. Supportive periodontal therapy (SPT) rate for each implant was calculated by dividing the number of SPT appointments by follow-up time (the time between T0 and Tf). SPT rate was 2.6 ± 1.4 (0–5) SPT/year. The majority of implants (87) were maintained more than twice per year on average (Table 2).

Table 2. Dental data.

Characteristics	T ₀	T _f
Mean patient <i>n</i> teeth (range)	21.8 ± 4.2 (10–29)	
Mean patient <i>n</i> implants (range)	1 ± 1.5 (0–5)	
Mean <i>n</i> PD ≥ 5mm (range)	6.7 ± 8.5 (0–40)	6.9 ± 9.2 (0–44)
FMBS (%) (range)	19.5% ± 15.4% (1–80%)	24.5% ± 16.3% (0–67%)
PI (range)	1.1 ± 0.4 (0.3–2)	1.3 ± 0.5 (0–2.5)
SPT/year		2.6 ± 1.4 (0–5)

4.3. Implant Data

A total of 142 implants were followed up to 23 years. Six implant brands were installed, which can be categorized in two main groups: the external hex group, consisting of 5 Brånemark® [Brånemark system® MKIII RP implant, Nobel Biocare AB, Göteborg, Sweden, (external hex, machined)], 8 3i® [Biomet 3i, Inc, Palm Beach Gardens, Florida, USA, (external hex, hybrid- machined top, dual acid etched bottom)], 5 Implant Direct® [Implant Direct, Valencia, CA, USA, (external hex, soluble blast medium blasted)], 11 MIS® [MIS Implant Technologies Ltd, Bar-Lev Industrial Zone, Israel, (external hex, sand-blasted, acid-etched)], 43 Steri Oss® [SteriOss Yorba Linda, CA, USA, (external hex, etched)], and the internal hex group, consisting of 70 Zimmer® [Zimmer Biomet Dental, Palm Beach Gardens, Florida, USA, (Internal hex, HA blasted)]. Implant length ranged between 10 mm and 16 mm, and their diameters ranged between 3.7 mm and 5mm. Seventy-five implants (52.8%) had an internal hex connection, whereas 67 (47.2%) had an external hex. One hundred thirty-six implants (96%) were placed in healed ridges (late implantation). Early and immediate implantation corresponded to 4 (2.67%) and 2 (1.33%) implants, respectively. Fifty-four implants (38%) received additional GBR, of which 12 (8.5%) had trans-crestal sinus augmentation and 32 (22.5%) had lateral window sinus augmentation. Ninety-nine (70%) were 10–12 mm long, and eighty-eight (62%) implants were 3.7–4 mm in diameter. A total of 53 (37%) implants were both 10–12 mm long and 3.7–4 mm in diameter.

All implant restorations were delayed loaded, predominantly fixed-multiple restorations (108 (76%)), with properly fitting margins (112 (78.9%)). Six (14.3%) presented overhanging margins, and 24 (16.9%) were ill-fitted showing radiographic gaps between the crown and the supra-structure.

In all cases, antagonists were existing. Fifty-four (38%) of the antagonists were intact teeth or teeth with plastic restorations (amalgam/composite), 23 (16.2%) were implants, and 58 (40.8%) were fixed restorations on either teeth or implants. Seven (5%) removable antagonists were recorded. (Table 3).

4.4. Radiographic Data

Radiographic bone loss is temporally associated; therefore, we chose to use the criterion of “excess bone loss” defined as 1.5 mm for the first year followed by 0.1 mm for each additional year for the construction of the model. One hundred and nine (76.8%) implants did not exhibit excess bone loss. Among patient related characteristics (e.g., age, gender, systemic health condition, and smoking) only osteoporosis was associated with excess bone loss ($p = 0.028$, OR = 4.69, CI 1.18–18.62). Moreover, clinical findings, including the number of teeth, number of sites with PD ≥ 5 mm, and plaque and bleeding scores, did not show any correlation with radiographic peri-implant bone loss. When it comes to implant-related data, only hex type, favoring external hex, was found to be borderline significantly correlated to radiographic peri-implant bone loss ($p = 0.059$, OR = 2.19, CI 0.97–4.96). Implant dimensions (diameter and length), GBR and sinus augmentation procedures were not associated with bone loss. Implant brands, type or quality of implant restoration, and type of

antagonist restoration were also not found to be significantly associated with radiographic peri-implant bone loss. Intra-examiner reproducibility of radiographic bone measurements showed concordance correlation coefficient [24] of 0.99 or almost perfect [25].

Table 3. Implants related data.

Characteristics	% (n)
Deepest PD at implant ($\leq 3/4-6/\geq 7$ mm)	49.3% (70)/42.3% (60)/8.4% (2)
BOP at implant (no/yes)	16.7% (22)/83.3% (110)
PII at implant (no/yes)	12% (7)/88% (125)
Timing of implantation (immediate/early/late)	95.8% (136)/2.8% (4)/1.4% (2)
Implant dimensions:	
Diameter (3.7–4mm/4.1–5mm)	62% (88)/38% (54)
Length (10–12mm/13–16mm)	69.7% (99)/30.3% (43)
GBR (no/yes)	62% (88)/38% (54)
Sinus augmentation (no/transcrestal/lateral window)	69% (98)/8.5% (12)/22.5% (32)
Restoration type (fixed single/multiple)	24% (34)/76% (108)
Restoration quality—proper/overhanging margin/ill-fitting margin (gap)	78.9% (112)/4.2% (6)/16.9% (24)
Antagonist (tooth/implant/fixed/removable)	38% (54)/16.2% (23)/40.8% (58)/5% (7)

4.5. Intervariable Interactions

Intervariable interactions were calculated prior to multivariate analysis. Bone loss was significantly lower among external hex implants, installed without GBR ($p = 0.008$, OR = 8, CI 1.71–37.42). Interestingly, no significant association between the connection type groups was found when implant installation was combined with GBR ($p = 0.811$). The significant difference between connection types existed only in the lower jaw ($p = 0.048$, OR = 3.49, CI 1.01–12.07). The number of teeth and the number of implants at T0 were significantly correlated with bone loss. When less than 20 teeth and 2 or more implants were present at T0, the odds-ratio for implant bone loss was 3.6 (CI 1.03–12.56), ($p = 0.045$). Implants having a length of 10–12 mm as well as a diameter of 3.7–4 mm were significantly more successful ($p = 0.033$, OR = 2.71, CI 1.08–6.79). (Table 4)

Table 4. Intervariable interactions.

Characteristics	% (n) * Excess Bone Loss	p Value	** OR	*** CI
With GBR				
ext. hex	29% (9)			
int. hex	26.1% (6)	0.811		
Without GBR				
ext. hex	5.4% (2)			
int. hex	31.4% (16)	0.008	8	1.71–37.42
T ₀ n Teeth and n Implants				
≥ 20 and < 2	11.8% (4)			
< 20 or ≥ 2	23.9% (17)	0.153		
< 20 and ≥ 2	32.4% (12)	0.045	3.6	1.03–12.56
Upper jaw				
ext. hex	20% (6)			
int. hex	27.1% (13)	0.48		
Lower jaw				
ext. hex	13.2% (5)			
int. hex	34.6% (9)	0.048	3.49	1.01–12.07
Implant dimensions

≤ 12 and ≤ 4	13.2% (7)			
> 13 or > 4	29.2% (26)	0.033	2.71	1.08–6.79

* excess bone loss—implants in which radiographic bone loss exceeded 1.5mm in the first year and 0.1 mm every additional year during the follow-up. ** OR—Odds Ratio. *** CI—Confidence Interval.

4.6. Mixed Logistic Regression

A combination of the following parameters was explanatory for implant bone stability: osteoporosis ($p < 0.007$, OR = 9.89, CI 1.85–52.8), smoking ($p < 0.048$, OR = 2.71, CI 1.01–7.27), external hex connection without GBR procedure ($p < 0.008$, OR = 11.98, CI 1.93–74.43), and implant diameter of 4 mm or less and length of 12 mm or less ($p = 0.021$, OR = 4.53, CI 1.25–16.38).

4.7. ROC Curve

The ROC curve (Figure 2) presents X and Y axes depicting, respectively, relative trade-offs between true positive (sensitivity) and false positive (1–specificity). The “goodness-of-fit” of the model was checked on each one of the implants. It was expressed as the Area Under the Curve (AUC). The AUC in the present model amounted to 76.9% (Standard Error 4.6%, CI 67.8%–86%).

Figure 2. Receiver operating curve (ROC) analysis for ‘goodness-of-fit’ of the found model for implant success. The area under the ROC curve (AUC) is significant ($p < 0.0001$).

5. Discussion

In the present study, external hex implants placed without bone augmentation presented with less long-term bone loss. The addition of bone augmentation procedures masked the effect of the connection type. Additionally, implants of 10–12 mm in length and of 3.7–4 mm in diameter presented less bone loss. The good AUC of the ROC model indicates its good fit. These findings partly support Jafarian et al [26], who reported that the brand, length, and diameter of implants affected the survival time, failure rate, and time to failure. In the Jafarian et al. study, implants with 10 mm length and 5.5–6 mm diameter had the highest failure rate; the lowest failure rate occurred in implants of 11.5 mm in length and 3–3.5 mm in diameter. In clinical practice, the choice of implant size is associated with the available bone volume and is at the discretion of the surgeon. Still, it seems that larger is not necessarily better when it comes to implant survival and success. Whereas large diameter seems to be a plausible factor contributing to the risk of peri-implant bone loss (the larger the diameter, the less thick the bone surrounding the implant), implant length does not seem an obvious risk. A possible explanation why long implants have a higher risk for bone loss is that bone heating from the drilling procedure is directly associated with the drilling depth (and implant length) [27].

Currently, there are variations in the criteria for acceptable bone loss during the various life stages of the implant. On the one hand, some report an acceptable bone loss of <0.5 mm as a common standard [28]; on the other hand, more recent publications define periimplantitis as bone level ≥ 3 mm

apical of the most coronal portion of the intra-osseous part of the implant [9]. The most reported criterion is that by Albrektsson et al., in which the mean bone loss over the first-year post implant installation up to 1.5 mm, and the subsequent loss per year around 0.1 mm, may be defined as acceptable [8]. Based on that, and taking into account an inherent mean error of 0.5 mm in bone level measurements [9] a minimum of six years, radiographic follow-up should be performed in order to detect bone loss in excess of 0.5 mm after the first year. We chose the 8-year lower inclusion threshold (and not 10 years or longer) in order to have a sample size large enough and with sufficient follow-up to obtain detectable bone loss.

Regarding connection type, our results were in line with much of the literature. Bone levels around external hex connection were stable and similar to [29,30] or smaller [31] than those observed at internal hex connection implants. Still, some publications favor internal hex connection implants regarding bone resorption [32–34]. It should be acknowledged that the connection type groups were composed of different brands with different implant surface-treatments, and possibly other differences as well; however, no significant statistical association was found between brand and bone loss. Similar conclusions were found by Lee et al. (2016) and Díaz-Sánchez et al. (2019) [35,36].

Osteoporosis is associated with an increase in peri-implant bone loss [37]. In our study, significantly more radiographic bone loss was observed in the two patients with osteoporosis that received nine implants. Although osteoporosis is not associated with increased implant loss, the present finding points to the need for further long-term investigation of implants in patients with osteoporosis.

Smoking has long been considered a risk factor for periodontal and peri-implant diseases, and in the present study smoking was found to be significantly correlated with peri-implant radiographic bone loss. Similar findings were reported in by Rinke et al. (2011) [11] and by Schwarz et al. (2017) [38], who reported odds ratio for periimplantitis among smokers of 2.7, similar to the present study.

Progression of peri-implantitis may have similarities with periodontitis; however, in the present study no association was found between factors traditionally associated with periodontitis such as FMBS, number of PD $\geq$ 5 mm, SPT rate, restoration related variables, and the observed peri-implant bone loss. This finding may be due to the fact that at least some patients may have had recurrent periodontal disease during the follow-up period. Contrary to the present study, in a systematic review by Lin et al. [39], it was shown that residual periodontal pockets and high levels of BOP and PI had a negative effect on peri-implant bone levels in patients with history of periodontitis and under regular SPT. The lack of association in the present study may be explained by SPT frequency, since 64.4% of the implants (87 implants) received SPT more than twice per year. The frequent maintenance utilized in the private practice masked the effect of poor oral hygiene on bone levels. In this study, all implants were rehabilitated with either single or multiple fixed restorations, none of which were associated with any difference in peri-implant bone loss. There were no overdenture patients to compare with; however, higher rates of marginal bone loss were reported among implants rehabilitated with overdentures vs. fixed restorations [40].

Weaknesses and strengths: The main drawbacks of the study are its retrospective design, the small sample size, and the heterogeneity in implant brands. Long-term retrospective studies often exhibit similar issues (with 75–101 implants in 26–63 patients and with up to seven implant brands) [13,41,42]. Additionally, restorations were performed by referring dentists, the uniformity of which was not controlled. Interestingly, the type of restoration or its apparent quality were not found to be associated with peri implant radiographic bone loss. Heterogeneity of implant systems can be considered a drawback but also an advantage, contributing to generalizability of the results regarding the lack of major differences in outcome between different implant systems of similar design [35,36].

6. Conclusions

Within the limitations of the study, the following conclusions can be made. Implants with an external hex placed without GBR and implants having a length of 10–12 mm as well as diameter of

3.7–4 mm showed less peri-implant radiographic bone loss in this long-term follow-up. Patients with osteoporosis and smokers were prone to increased radiographic peri-implant bone-loss.
