Abstract: The purpose of this paper is to numerically simulate the breaking wave past a standing cylinder with different transverse inclined angles. The numerical simulations are carried out by solving the Unsteady Reynolds-Averaged Navier–Stokes (URANS) equations with the $k - \omega$ SST turbulence model. The air–water interface is captured using the Volume of Fluid (VOF) method. The convergence studies on the grid and time-step are performed by examining the total horizontal breaking wave forces on the vertical cylinder. The present numerical results have been validated with the published experimental data. A good agreement is obtained between the present numerical results and the experimental data in terms of the surface elevation and the horizontal breaking wave force. Moreover, the total horizontal breaking wave force is decomposed into low-order and high-order wave forces through Fast Fourier Transform (FFT). It is observed that the free surface elevations in front of the cylinder and the normalized high-order wave force have a minimum value when the transverse inclined angle of the cylinder is 45° . The secondary load causing the higher-harmonic ringing motion of structures is not observed when the cylinder is placed with the transverse inclined angles of 30° and 45° .

Keywords: breaking wave; inclined cylinder; $k - \omega$ SST turbulence model; computational fluid dynamics

1. Introduction

The offshore structures installed in shallow water usually suffer highly nonlinear wave breaking impacts. Many coastal and offshore structures consist of cylinders with different inclined angles, such as supporting structures of wind turbines, platforms, and large floating bridges. The breaking waves normally hit the structures within a very short duration and cause a large wave impact force, which can lead to a significant damage to the structures. Therefore, accurately predicting the wave impact forces on standing cylindrical structures with different inclined angles is of great concern for the design of coastal and offshore structures. Because the characteristics of wave breaking are strongly nonlinear, most early research was mainly based on experimental investigations. Apelt and Piorewicz [1] performed breaking wave force experiments on two and three vertical cylinders situated in the breaking wave zone parallel and normal to the direction of wave propagation. The experimental results showed that the incident wave steepness and the distance between the cylinders were two important factors, especially when the cylinders are arranged in orientations normal to the wave propagation than parallel to the wave propagation. Wienke et al. [2] conducted large-scale experimental

studies on breaking wave impacts on a vertical cylindrical pile. It was presented that the total breaking wave force is the sum of the quasi-static force calculated by the Morison equations and the slamming force considering the duration of the impact. Irschik et al. [3] employed the Fast Fourier Transform (FFT) low-pass filter and the Empirical Mode Decomposition (EMD) to separate the experimental data of breaking wave forces on a vertical cylinder into two components, i.e., the quasi-static loading and the dynamic force. They found that the calculation methods overestimated the quasi-static force in the region of the maximum impact.

However, measuring velocity, acceleration, and turbulent properties during wave breaking are challenging tasks in the experiment [4]. Moreover, the appropriate experimental facilities, as well as minimizing human and instrument errors have important influences on experimental results. With the increase in computational capabilities, a good alternative approach is Computational Fluid Dynamics (CFD), which can be applied to simulate the impact of the breaking waves on marine structures for both research and engineering design purposes.

Christensen et al. [5] used a Navier–Stokes solver with the VOF technique to study the wave run-up and breaking wave forces on a vertical cylinder. They found that the peak value of the horizontal breaking wave force under a plunging breaker was much larger than that under a spilling breaker. Shao [6] employed the incompressible smoothed particle hydrodynamic (ISPH) method coupled with $k - \varepsilon$ turbulence model to simulate the spilling and plunging waves by solving RANS equations. It was found that the SPH method can accurately capture the free surfaces without the numerical diffusion compared with the Euler grid method. Chow et al. [7] simulated non-breaking and breaking waves past a vertical cylinder with the improved ISPH method. They found that the maximum loading on the structure was related to the free surface elevation and steepness of the wave across the cylinder. Local pressures on the cylinder near the free surface under breaking waves are higher than those of non-breaking waves. Bredmose and Jacobsen [8] computed breaking wave forces on wind turbines using the VOF method without considering turbulence effects. Their results suggest that the peak force become smaller when the breaking wave is more developed for the spilling breakers. Xiao and Huang [9] investigated the wave run-up and breaking wave impacts on a vertical cylinder located at different positions using the $k - \varepsilon$ turbulence model with the VOF method. In their study, the largest wave force was observed when the pile was located at $3/4 R$ (R is the maximum run-up height) below the shoreline. Choi et al. [10] studied breaking wave impact forces on the vertical cylinder and the inclined cylinder which direction is parallel to the wave propagation using modified Navier–Stokes equations. The effect on the breaking wave forces due to the vibration of cylinders in the experiment was studied. The computed breaking wave forces were in good agreement with the experimental data filtered by an FFT low-pass filter and EMD. Kamath et al. [11] and Chella et al. [12] studied the influence of wave breaking locations on the interactions between breaking waves and a vertical cylinder using the $k - \omega$ turbulence model. They pointed out that the largest total horizontal wave force was generated when the overturning wave tongue was just below the wave crest level and hit the cylinder. Jose and Choi [13] investigated the slamming coefficients on the local cylindrical members of a jacket structure under plunging breakers by solving Navier–Stokes equations together with the VOF method. It was found that the maximum slamming coefficients increase first and then decrease in the impact area, and the curves presented triangular shapes. It is recommended that when calculating the slamming force on the offshore wind turbine substructures, a triangular distribution of force should be adopted instead of using the maximum value of slamming force along the entire member. Recently, Liu et al. [14,15] employed the $k - \omega$ SST turbulence model with the VOF method to study the higher-harmonic force on a vertical cylinder under the breaking wave impact. The numerical results show that the occurrence of the secondary load cycles was related to the Froude number and the wave steepness. Both slamming wave force and secondary load can generate the higher-harmonic wave force in the case of breaking wave.

Based on a review of the literature, most studies focused on the effects of wave steepness, wave breaking location, and different numerical models. Only a few papers investigated the influence

of inclined angles of the cylinder parallel to the direction of wave propagation. However, for assessment on the stability and safety of the structures during the engineering design process, it is important to understand the interaction between the breaking waves and the cylinders with different inclined directions. Therefore, the primary purpose of the present study is to investigate the characteristics of breaking wave forces on a standing cylinder with different transverse inclined angles in orientation normal to the wave propagation. In this paper, URANS equations are solved by using an open-source CFD software Open FOAM. The interface between air and water is captured using the VOF method. This paper is structured as follows. First, the convergence studies on the grid and time-step are presented. Then numerical results of total horizontal breaking wave forces on the cylinder and free surface elevations are compared with the published experimental data to validate the accuracy of the numerical model. Furthermore, the characteristics of the free surface elevations and different compositions of wave forces are studied. The effects of the transverse inclined angle are discussed in detail. Finally, the conclusions based on the present numerical results are summarized.

2. Methodology

2.1. Governing Equations

The air and water phases are treated as incompressible viscous fluid in the present numerical model, which are solved using URANS equations:

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p_{rgh}}{\partial x_i} + \nu \frac{\partial^2 u_i}{\partial x_j^2} - \frac{\partial \overline{u'_i u'_j}}{\partial x_j} \tag{1}$$

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{2}$$

where u_i are the components of the mean fluid velocity, p_{rgh} is the pressure in excess of the static pressure, ρ is the fluid density (air or water), and ν is the kinematic viscosity. $\overline{u'_i u'_j}$ denotes the Reynolds stress component expressed by the Boussinesq approximation.

$$\overline{u'_i u'_j} = \nu_t \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - \frac{2}{3} k \delta_{ij} \tag{3}$$

Here, k is turbulent kinetic energy, ν_t is the turbulent kinematic viscosity, and δ_{ij} is the Kronecker delta.

The $k - \omega$ SST model proposed by Menter [16] has a good performance for wave elevation predictions during the wave breaking according to Brown et al. [17]. The application of the $k - \omega$ SST model to numerically simulate breaking wave past a vertical cylinder can also be found in Liu et al. [14,15]. Therefore, the $k - \omega$ SST turbulence model is employed in the present simulations. The transport equations for turbulent kinetic energy k and specific turbulent dissipation rate ω are given by

$$\frac{\partial(\rho k)}{\partial t} + \frac{\partial(\rho u_i k)}{\partial x_i} = \frac{\partial}{\partial x_i} \left[(\mu + \sigma_k \mu_t) \frac{\partial k}{\partial x_i} \right] + P_k - \beta^* \rho \omega k \tag{4}$$

$$\frac{\partial(\rho \omega)}{\partial t} + \frac{\partial(\rho u_i \omega)}{\partial x_i} = \frac{\partial}{\partial x_i} \left[(\mu + \sigma_\omega \mu_t) \frac{\partial \omega}{\partial x_i} \right] + \alpha \rho S^2 - \beta \rho \omega^2 + 2(1 - F_1) \frac{\rho \sigma_\omega 2}{\omega} \frac{\partial k}{\partial x_i} \frac{\partial \omega}{\partial x_i} \tag{5}$$

where F_1 is the first blending function defined as

$$F_1 = \tanh \left\{ \left\{ \min \left[\max \left(\frac{\sqrt{k}}{B^* \omega y'}, \frac{500 \nu}{y^2 \omega} \right), \frac{4 \rho \sigma_\omega 2 k}{CD_{k\omega} y^2} \right] \right\}^4 \right\} \tag{6}$$

$$CD_{k\omega} = \max \left(2 \frac{\rho \sigma_\omega 2}{\omega} \frac{\partial k}{\partial x_i} \frac{\partial \omega}{\partial x_i}, 10^{-10} \right) \tag{7}$$

where y is the distance from the center of the first layer mesh to the wall. The dynamic turbulent viscosity μ_t is defined by

$$\mu_t = \frac{\rho a_1 k}{\max(a_1 \omega, SF_2)} \tag{8}$$

The invariant measure of the strain rate $S = \sqrt{2S_{ij}S_{ij}}$. Here, $S_{ij} = \frac{1}{2}(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i})$. The second blending function F_2 is expressed as

$$F_2 = \tanh\left[\left[\max\left(\frac{2\sqrt{k}}{\beta^* \omega y}, \frac{500\nu}{y^2 \omega}\right)\right]^2\right] \tag{9}$$

The production term $P_k = \min(G, 10\beta^* \rho k \omega)$, where G is given by

$$G = \mu_t \frac{\partial u_i}{\partial x_j} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \tag{10}$$

The constants of $\alpha_k, \alpha_\omega, \alpha$ and β are blended using equation

$$\phi = F_1 \phi_1 + (1 - F_1) \phi_2 \tag{11}$$

The constants of this model are $\beta^* = 0.09, \alpha_1 = 5/9, \beta_1 = 0.075, \sigma_{k1} = 0.85, \sigma_{\omega1} = 0.5, \alpha_2 = 0.44, \beta_2 = 0.0828, \sigma_{k2} = 1, \sigma_{\omega2} = 0.856$.

2.2. Free Surface Capture

The interface between the air and the water is captured by the VOF method [18], which is based on a volume fraction coefficient α defined as

$$\alpha = \begin{cases} \alpha = 1 & \text{water} \\ 0 < \alpha < 1 & \text{interface} \\ \alpha = 0 & \text{air} \end{cases} \tag{12}$$

The density ρ and kinematic viscosity ν at the interface can be obtained based on the formulas as follows,

$$\begin{cases} \rho = \alpha \rho_w + (1 - \alpha) \rho_a \\ \nu = \alpha \nu_w + (1 - \alpha) \nu_a \end{cases} \tag{13}$$

where ρ_a and ρ_w are the densities of air and water, respectively; ν_a and ν_w denote the kinematic viscosity coefficients of air and water, respectively. The volume fraction α is solved by the following advection equation,

$$\frac{\partial \alpha}{\partial t} + \frac{\partial(\alpha u_i)}{\partial x_i} + \frac{\partial[\alpha(1 - \alpha)u_{ir}]}{\partial x_i} = 0 \tag{14}$$

where u_{ir} denotes the relative velocity between air and water in the interface region. The surface tension effect is considered negligible.

2.3. Numerical Wave Tank

A relaxation method presented by Mayer et al. [19] is used to generate and absorb waves in the numerical wave tank. The relaxation algorithm [20] used to update the wave height and the velocity in the generation zone and absorption zone is expressed as

$$\phi = \gamma_R \phi_{computed} + (1 - \gamma_R) \phi_{target} \tag{15}$$

where ϕ is either α or u_i , and the weighting factor γ_R is defined by

$$\gamma_R = 1 - \frac{\exp(\chi_R^{3.5}) - 1}{\exp(1) - 1}, \chi_R \in [0, 1] \quad (16)$$

The set-up of the numerical wave tank is shown in Figure 1. Both the wave generation zone and the absorption zone are one wavelength long, respectively. The transverse inclined angle θ is defined as the angle between the cylinder and the vertical direction at the plane perpendicular to the direction of wave propagation.

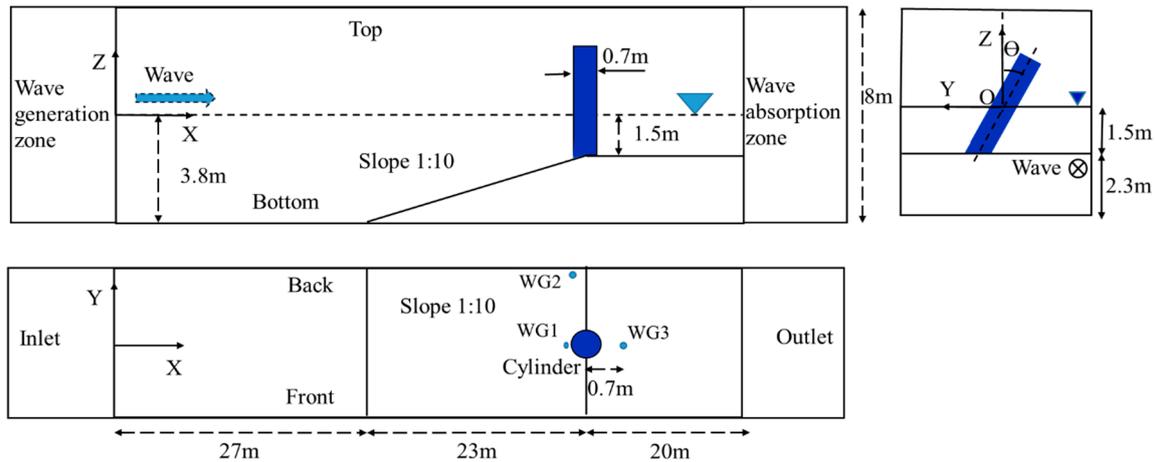

Figure 1. The layout of the numerical wave tank: front view (top); side view (right); plan view (bottom).

2.4. Boundary Conditions

Boundary conditions of the present numerical wave tank are presented as follows.

- (i) At the inlet boundary, the velocity for the water is given according to the wave theory, while the air velocity is zero. The pressure is set as a zero normal gradient boundary condition.
- (ii) At the outlet of the domain, the velocities for both water and air are set to zero. The zero normal gradient condition is applied for the pressure.
- (iii) At the top boundary, the velocity for the inflow is calculated from the flux in the patch-normal direction. The velocity for the outflow is set as the zero normal gradient boundary condition. The patch pressure p_p on the top boundary is obtained by subtracting the dynamic pressure from the total pressure, expressed as follows,

$$p_p = p_0 - 0.5|\mathbf{u}|^2 \quad (17)$$

where p_0 is total pressure and \mathbf{u} is the mean velocity vector.

- (iv) The no-slip condition is employed in four boundaries, i.e., front, back, bottom, and the cylinder's surface, where the velocity is zero. Meanwhile, the wall functions are employed on these boundaries. The distance of the first layer center to the wall is $0.002 D$, where D is the diameter of the cylinder. It ensures that the dimensionless wall distance y^+ for the present simulation is at the range of 40–200.

2.5. Calculation of Wave Forces

The breaking wave forces on the cylinder are calculated as the integral of the pressure and the normal component of viscous shear stress τ on the surface of the cylinder Ω :

$$F = \int_{\Omega} (-np + \mathbf{n} \cdot \tau) d\Omega \quad (18)$$

where \mathbf{n} is the unit normal vector pointing to the interior of the fluid.

2.6. Numerical Scheme

In the present simulations, the governing equations are discretized by the finite volume method (FVM). The PISO-SIMPLE (PIMPLE) algorithm is employed for the pressure-velocity coupling. The time derivatives are solved by the second-order implicit Crank-Nicolson scheme. Second-order Gauss with a limited linear scheme is employed for the convective terms. Second-order Gauss with a linear scheme is employed for the diffusive terms. The generalized geometric-algebraic multi-grid (GAMG) numerical method with Diagonal-based Incomplete Cholesky (DIC) preconditioner is employed to solve the pressure equations. For more details information of the above numerical scheme, please refer to Open FOAM [21].

3. Numerical Implementation

3.1. Setup of the Numerical Wave Tank

The experiments were performed at the Large Wave Channel (GWK) in Hannover, Germany. The dimensions of the wave flume are 309 m long, 7 m high, and 5 m wide with a 1:10 slope at the bottom. A cylinder with the diameter $D = 0.7$ m was installed with its central axis at the edge of the slope. More details of the experiments can be seen in Irschik et al. [3]. The configuration of the present three-dimensional numerical wave tank (NWT) is based on the experimental setup, as shown in Figure 1. The length and height of the NWT working zone are 70 m and 8 m, respectively. The width of the whole computational domain varies with the transverse inclined angle θ , ensuring that both ends of the cylinder are at least $4D$ away from the front and back boundaries. Three numerical wave gauges (WG1, WG2, and WG3) are used to measure the free surface elevations η , i.e., WG1 is mounted at 0.01 m in front of the cylinder, WG2 is placed near the wall along the frontline of the cylinder and WG3 is arranged at 0.7 m behind the cylinder. The specific positions of wave gauges can be seen in Figure 1. In this study, six cases with different transverse inclined angles are simulated, as shown in Table 1. The incident wave height $H = 1.3$ m, wave period $T = 4.0$ s, and water depth $d = 3.8$ m are chosen for all the simulations.

Table 1. Overview of six cases with different transverse inclined angles ($H = 1.3$ m, $T = 4.0$ s, $d = 3.8$ m).

Case	Transverse Inclined Angle θ ($^\circ$)
A	0
B	15
C	30
D	45
E	60
F	75

3.2. Grid and Time-Step Refinement Studies

In this section, three sets of meshes are performed to do a grid convergence study as shown in Table 2. All the present numerical simulations are conducted for a minimum duration of 140 s (35 wave periods), which ensures that the stable results can be obtained.

Table 2. The resolutions of three different meshes.

Mesh	Near the Cylinder (m) Max(Δx , Δy , Δz)	At Wave Generator (m) Max(Δx , Δy , Δz)	Number of Total Grids
Coarse mesh	(0.12, 0.1, 0.08)	(0.15, 0.10, 0.08)	5,791,152
Medium mesh	(0.10, 0.06, 0.05)	(0.12, 0.08, 0.05)	7,787,600
Fine mesh	(0.08, 0.06, 0.045)	(0.10, 0.08, 0.045)	8,564,864

Figure 2 shows the total horizontal breaking wave forces F_T on the vertical cylinder ($\theta = 0^\circ$) with three different meshes over one wave period. The relative difference in peak value of the F_T between the fine mesh and the medium mesh is 2.2%, which is considered sufficiently accurate for the present simulations. Moreover, there finement study on time-step is also carried out by changing the maximum Courant number. It can be seen from Figure 3 that there is no significant improvement for F_T when the maximum Courant number decreases from 0.5 to 0.3. Therefore, the medium mesh with the maximum Courant number 0.5 is considered to give sufficient accuracy to capture the horizontal breaking wave forces and will be used for all other cases. The different views of the medium mesh near the vertical cylinder are shown in Figure 4.

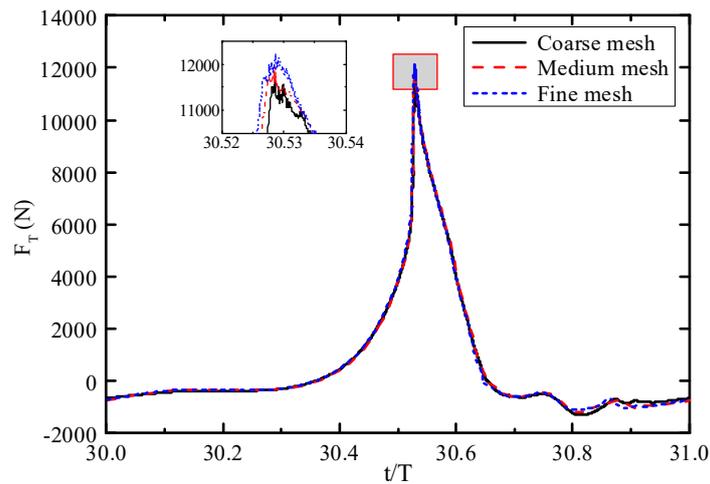

Figure 2. Grid refinement study for the breaking wave forces on the vertical cylinder.

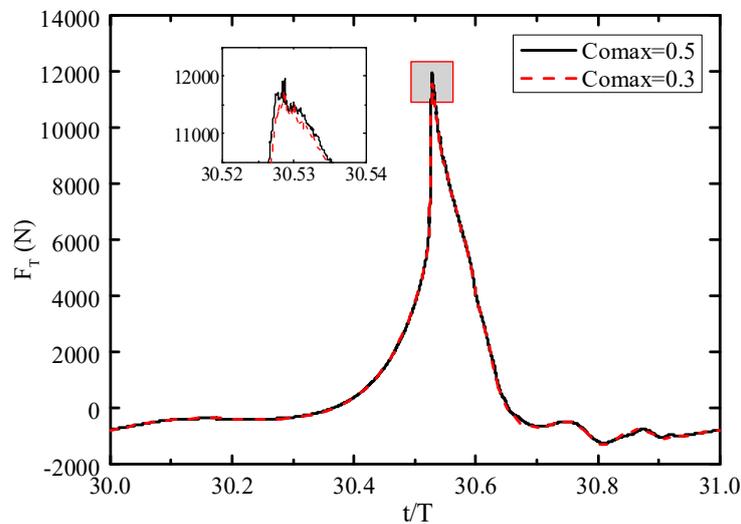

Figure 3. Time-step refinement study for the breaking wave forces on the vertical cylinder.

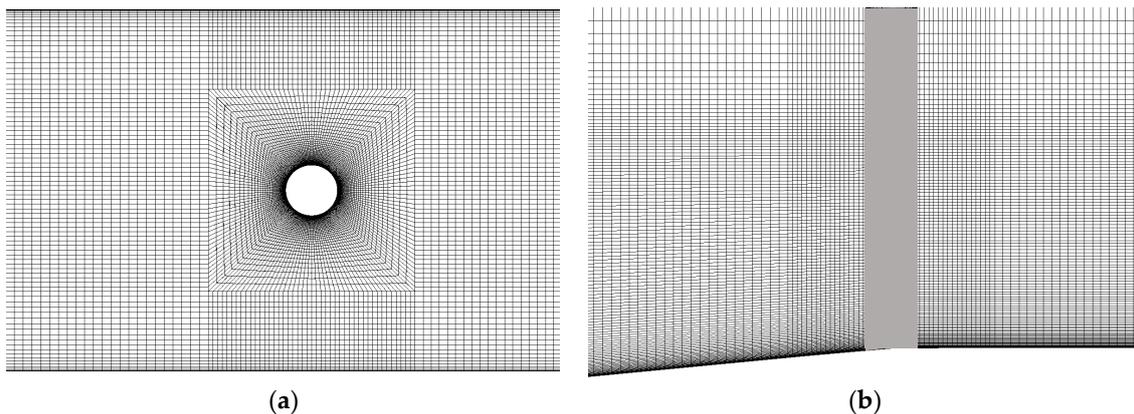

Figure 4. The plan view (a) and front view(b) of the medium mesh near the vertical cylinder.

4. Results

4.1. Validation of the Numerical Model

In this section, validation studies are conducted through the numerical simulations of breaking waves past a vertical cylinder and an inclined cylinder with $\varphi = -22.5^\circ$. φ is defined as the inclined angle parallel to the direction of wave propagation, details can be seen the set-up in Irschik et al. [3]. The present numerical results of the free surface elevations at the WG2 and the F_T are compared with the experimental data from Irschik et al. [3], presented by Choi et al. [10] and other published computed results to validate the accuracy of the present model.

4.1.1. Comparisons of the Present Numerically Simulated Results with the Published Data for a Vertical Cylinder

Figure 5 shows the comparison of the present predicted free surface elevations η at the WG2 location and published data for the vertical cylinder. The present result is in good agreement with the experimental data and the numerical results from Choi et al. [10] and Kamath et al. [11] except for the slight discrepancy at around $t/T = 31.1$. This could be explained as given below. In the experiment, the wave gauges were installed near the wave tank sidewall to avoid the influence of the measurement equipment on the waves. The interactions between the wave tank sidewall and the wave gauges, as well as the interactions between different wave gauges, can affect the free surface around the measure locations. Figure 6 shows the comparison of the F_T on the vertical cylinder over one wave period between the present numerical simulation and the published data. The present computed result of the F_T agrees best with the experimental data compared with other numerical simulated results. Meanwhile, the numerical computed rise times obtained by present simulation, Choi et al. [10] and Kamath et al. [11] are ahead of the experimental data at approximately $t/T = 30.4$. The reason for this is that the assumptions of incompressible flow and rigidly fixed cylinders are applied in the present numerical simulations. However, in the experiment, cylinder vibration, surface irregularities, compressibility of the flow during the impact, and water droplets on the surface of the cylinder may have an effect on the rise time (Choi et al. [10]).

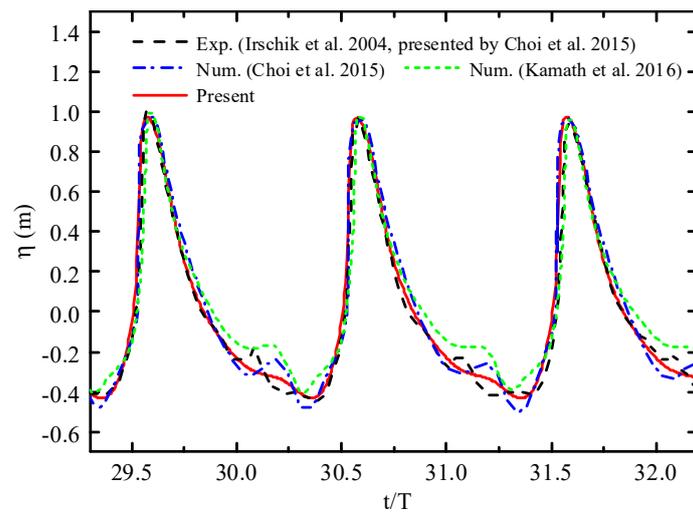

Figure 5. Comparison of free surface elevations at WG2 between the present result and the published data for the vertical cylinder.

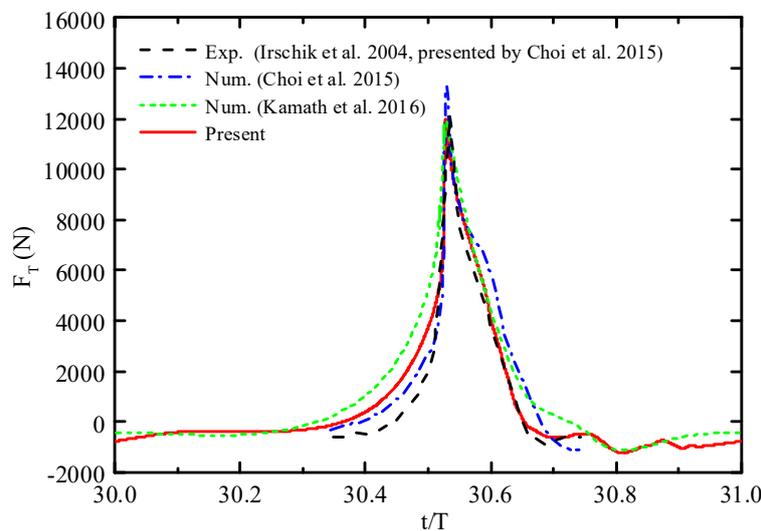

Figure 6. Comparison of breaking wave forces between the present result and the published data for the vertical cylinder.

4.1.2. Comparisons of the Present Numerically Simulated Results with the Published Data for an Inclined Cylinder

Figures 7 and 8 show the comparisons between the numerical results and the experimental data in terms of the free surface elevations at WG2 location and the F_T on the cylinder with inclined angle $\varphi = -22.5^\circ$, respectively. The present predicted free surface elevation agrees reasonably well with the published experimental data. A good agreement is generally observed between the present numerical results and the published experimental data for the F_T in Figure 8. The peak value of the F_T calculated by present model is slightly overestimated as compared with the experimental peak value, but smaller than the numerical result obtained by Choi et al. [10]. The slight discrepancy can also be seen for the rise times of wave forces at around $t/T = 30.4$ between the numerical simulations and the experimental data. Apart from the reasons mentioned in Section 4.1.1, another critical factor that cannot be ignored is the inclined angle of the cylinder. The rise time and peak value of the force are very sensitive to the inclined angle of the cylinder. In the experiment, the vibration of the cylinder caused by the large wave impact force can change the initial position of the cylinder, which may introduce the measurement inaccuracy.

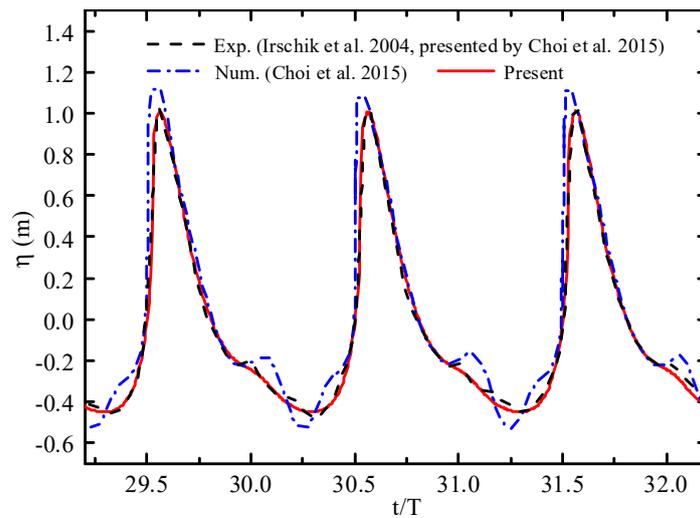

Figure 7. Comparison of free surface elevations at WG2 between the present result and the published data for the inclined cylinder ($\varphi = -22.5^\circ$).

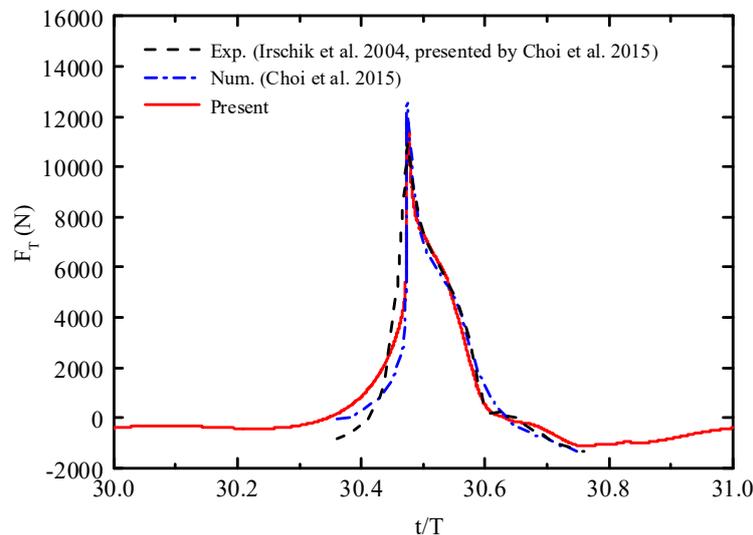

Figure 8. Comparison of breaking wave forces between the present result and the published data for the inclined cylinder ($\varphi = -22.5^\circ$).

The two conducted validation studies show that the present numerical model has good performance in predicting free surface elevations and breaking wave forces on the vertical and inclined cylinders. Therefore, the present model is also considered to give reasonable accuracy for simulating breaking wave past a cylinder with different transverse inclined angles.

4.2. Characteristics of the Free Surface Elevations and the Breaking Wave Forces on the Standing Cylinder with Different Transverse Inclined Angles

In this section, the free surface elevations and the wave forces on the cylinder with different transverse inclined angle θ are studied. Note that the transverse inclined angle θ is different from the angle φ mentioned in Section 4.1.2. θ is the inclined angle normal to the wave propagating direction and φ is the inclined angle parallel to the wave propagating direction.

Figure 9 depicts the variations of the free surface elevations at WG1 and WG3 locations over one wave period. The peak value of the free surface elevation for the vertical cylinder ($\theta = 0^\circ$) is significantly higher than that for cylinders with other transverse inclined angles at WG1 location. The relative difference of the wave height is reduced by 48.8% when the angle θ varies from 0° to 45° . A small part

of the water mass will be reflected due to the existence of the cylinder. Therefore, the second peak of the free surface elevation is also observed in Figure 9a. The maximum value of the wave height at WG3 occurs when the breaking wave passes the vertical cylinder ($\theta = 0^\circ$). Figure 10 shows the peak values of the free surface elevations at WG1 and WG3 for the cases of the cylinder with different θ . The free surface elevation at WG1 decreases first and then increases slightly. The minimum surface elevation is obtained at $\theta = 45^\circ$. The free surface elevation at WG3 gradually decreases with θ varying from 0° to 30° and increases when θ increases from 30° to 75° . This can be explained as given below. When the breaking wave passes a standing cylinder, it will produce a chute-like jet at the back of the cylinder. The height of the chute-like jet is related to transverse inclined angle of the cylinder and decreases with increasing θ . This is the reason that the free surface elevation at WG3 reduces first. With the further increase of θ , the cylinder's resistance to waves in the vertical direction is weaker, and waves can propagate more easily through the cylinder, which increases the surface elevation.

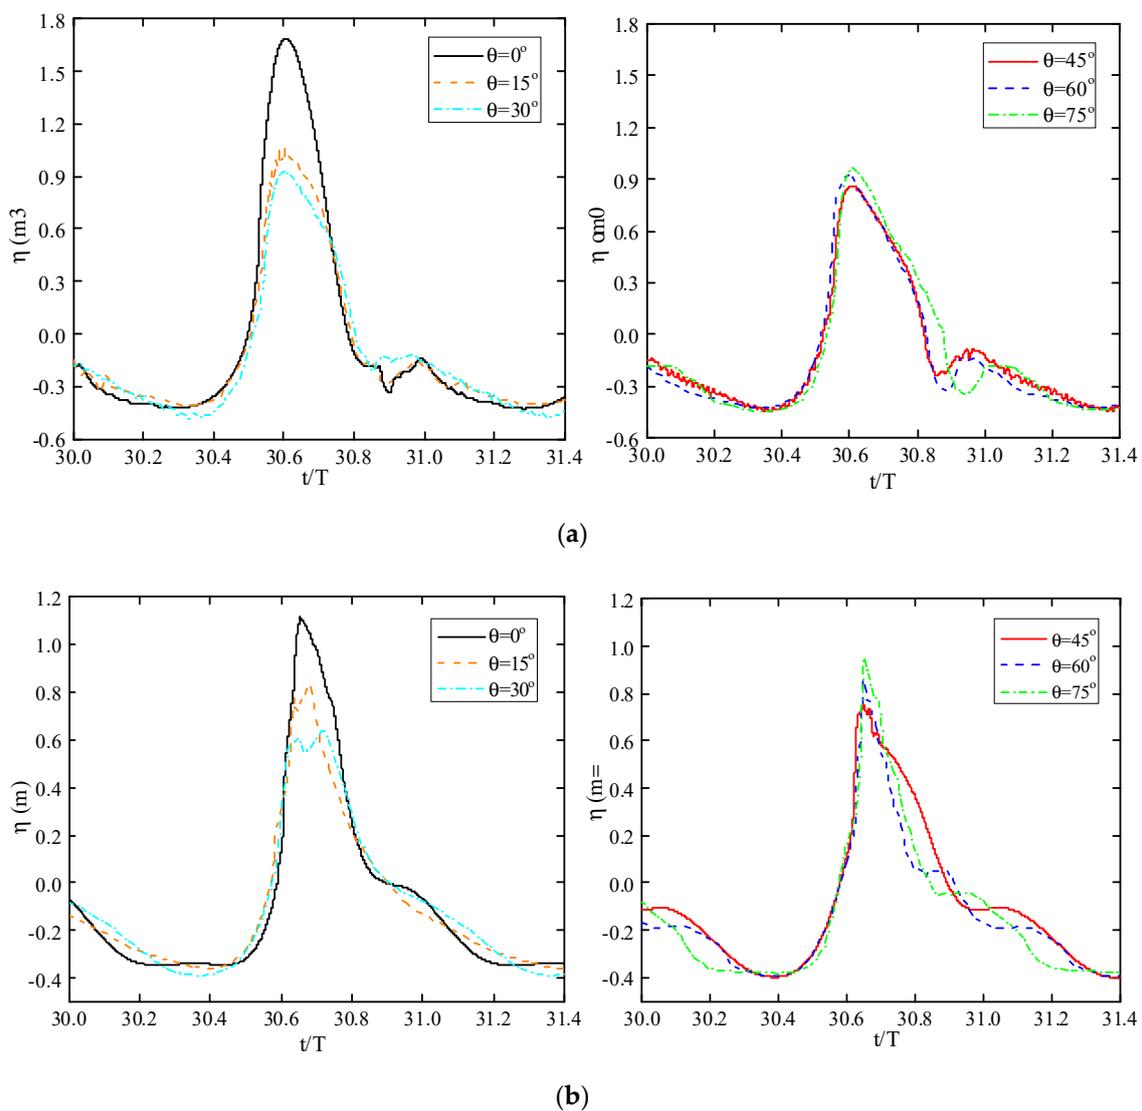

Figure 9. Variations of the free surface elevations around the cylinder with normalized time: (a) free surface elevations before the cylinder (WG1); (b) free surface elevations behind of cylinder (WG3).

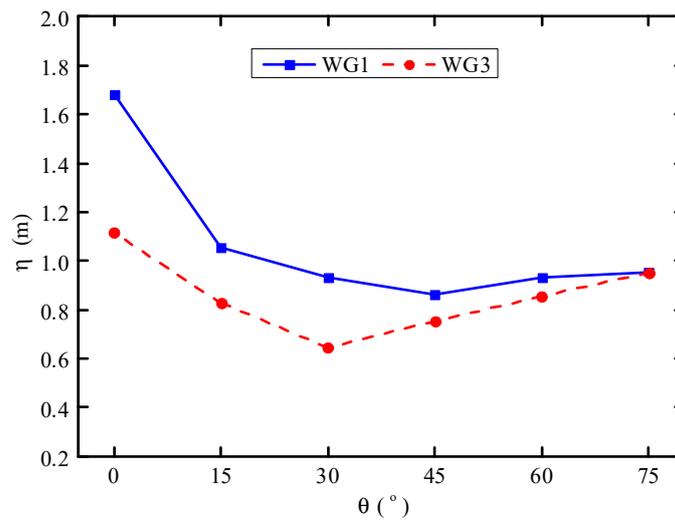

Figure 10. Comparison of the peak values of the free surface elevations around the cylinder with different transverse inclined angles θ .

The forces on the cylinder are normalized by $F' = F_c / (0.5\rho_{water}(L/T)^2S_h)$, where F_c represents different compositions of wave forces, L is the wavelength, and S_h is the submerged projected area in the direction of wave propagation. Figure 11 shows the normalized F_T on the cylinder versus θ over one wave period. The peak of the normalized F_T is the largest for the case of the cylinder with $\theta = 0^\circ$. Besides, the secondary load is generated when $\theta = 0^\circ, 60^\circ$ and 75° , which are closely associated with the higher-harmonic ringing motion of the cylinder and cause the fatigue and damage of structures [22]. However, the secondary loads cannot be observed for the cases of $\theta = 30^\circ$ and $\theta = 45^\circ$, which has a positive effect on the design and installation of cylindrical marine structures.

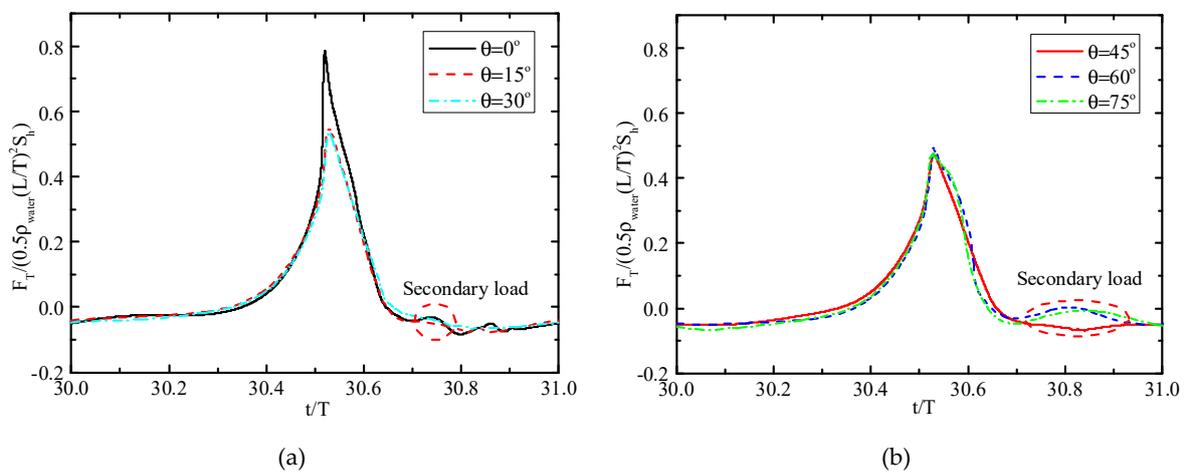

Figure 11. Variation of the normalized horizontal breaking wave forces on the cylinder in different transverse inclined angles. (a) $\theta = 0^\circ, 15^\circ, 30^\circ$; (b) $\theta = 45^\circ, 60^\circ, 75^\circ$.

To further analyze the breaking wave forces characteristics, the total horizontal breaking wave force is decomposed into two parts by using Fast Fourier Transform (FFT), i.e., low-order (first and second orders) wave force F_L and high-order wave force F_H . Figure 12 depicts the variations of the normalized F_L versus θ over one wave period. The normalized F_L do not change significantly when the cylinder is placed with different θ . However, the variation of θ has important influence on the normalized F_H . It can be seen from Figure 13 that the peak value of the normalized F_H on the cylinder with $\theta = 0^\circ$ is significantly higher than that for other θ . This implies that the strongest impact phenomenon occurs when the cylinder is perpendicular to the seafloor.

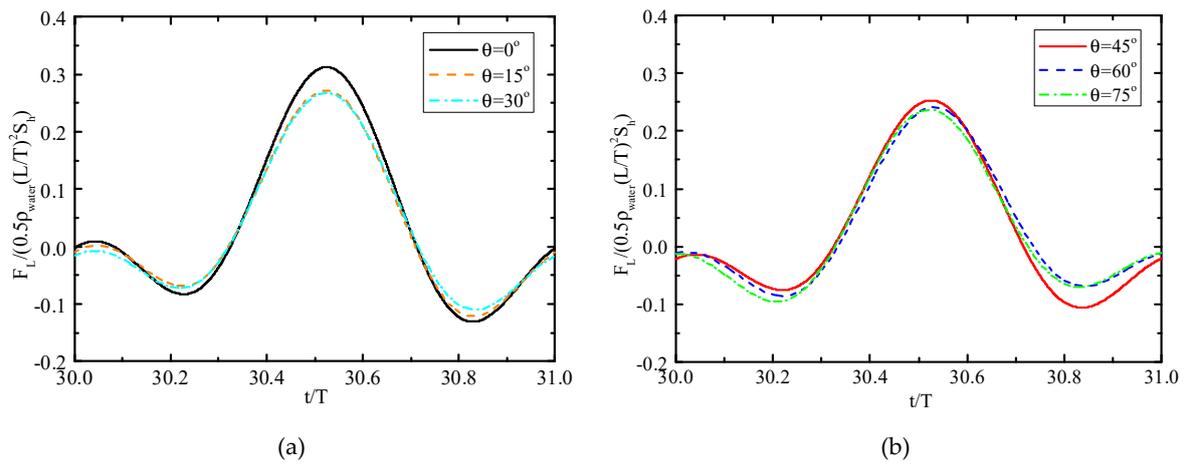

Figure 12. Variation of the normalized low-order wave forces on the cylinder in different transverse inclined angles. (a) $\theta = 0^\circ, 15^\circ, 30^\circ$; (b) $\theta = 45^\circ, 60^\circ, 75^\circ$.

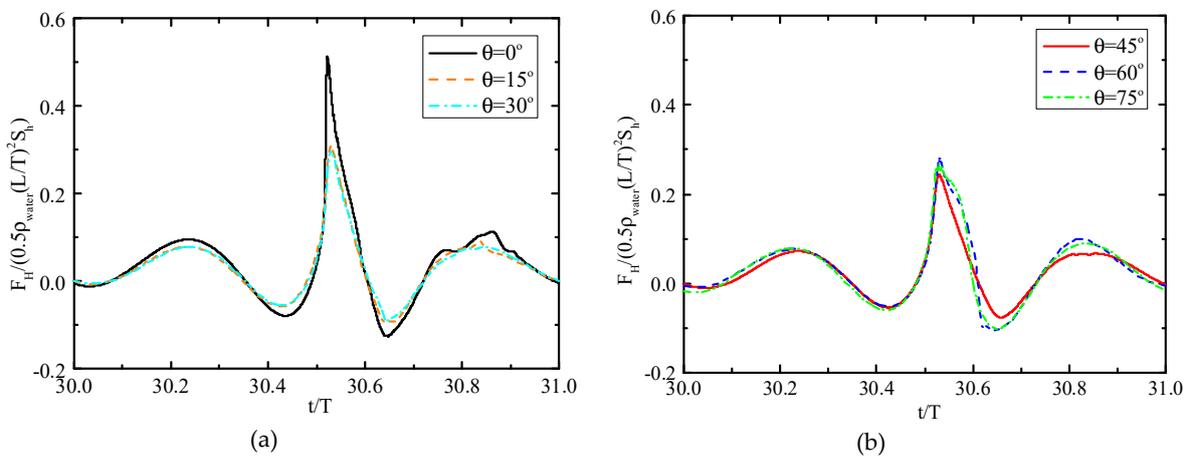

Figure 13. Variation of the normalized high-order wave forces on the cylinder in different transverse inclined angles. (a) $\theta = 0^\circ, 15^\circ, 30^\circ$; (b) $\theta = 45^\circ, 60^\circ, 75^\circ$.

Figure 14 shows the peak values of the normalized wave forces (F_T, F_H and F_L) on the cylinder versus θ . The normalized F_T has a sharp reduction for θ varying from 0° to 15° and then decreases gently as $\theta > 15^\circ$. However, a relatively small value of the normalized F_T is obtained at $\theta = 45^\circ$. The value of the normalized F_T decreases 40.9% when θ increases from 0° to 45° . For the normalized F_H , the similar trend of the curve can be observed with the normalized F_T . The normalized F_H decreases with θ varying from 0° to 45° first, and then increases with θ increasing from 45° to 75° . The minimum value is also observed for the case of $\theta = 45^\circ$. The normalized F_L decreases slightly as θ increases. When the cylinder is placed with $\theta = 45^\circ$, the ratio of the normalized F_H to the normalized F_T is also the minimum, i.e., 51.95%. At the same time, the normalized F_L and the normalized F_H have almost equal contributions to the normalized F_T for the case of $\theta = 45^\circ$. It is advantageous for ocean engineering support structures designed as $\theta = 45^\circ$ so that the minimal value of the normalized wave forces are obtained. Moreover, the peak values of different compositions forces in different θ are shown in Table 3. The wave forces (F_T, F_H and F_L) increase as θ increases apart from $\theta = 0^\circ$. As shown in Figure 13, the main peak of the high-order wave force corresponds the peak of the impact force. Therefore, it is considered that the main component of the high-order wave force is from the wave impact force on the cylinder. Under the same incident waves, the high-order wave force is mainly dependent on the maximum pressure on the cylinder. Comparing Figures 15b and 16b, the maximum pressure on the vertical cylinder is higher than that on the inclined cylinder with $\theta = 45^\circ$. Therefore, the larger high-order wave force on the vertical cylinder is observed at $\theta = 0^\circ$, where as the low-order wave

force mainly depends on the area of the cylinder in contact with the wave. The larger submerged area gives the large low-order wave force when θ increases. For the case of vertical cylinder ($\theta = 0^\circ$), the free surface elevation is the highest due to the large wave reflection from the cylinder as shown in Figure 10, which leads to a larger wet surface area as compared to the other transverse inclined angles. Therefore, the large low-order wave force is generated at $\theta = 0^\circ$.

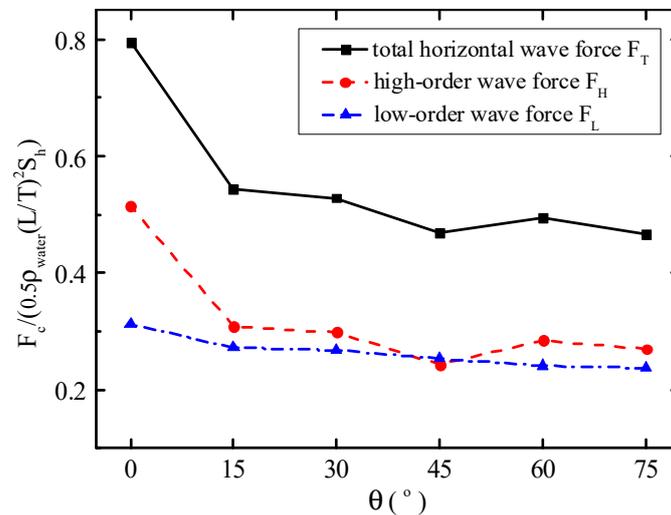

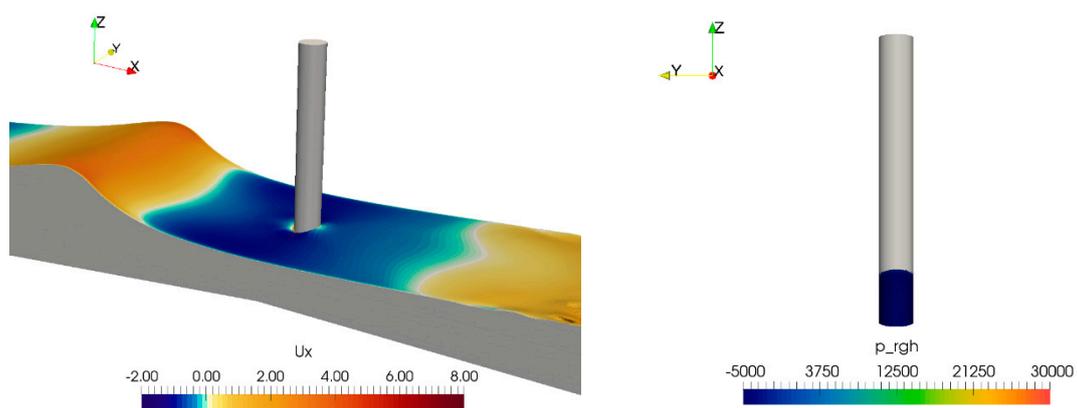

Figure 14. Comparison of the maximum normalized wave forces with transverse inclined angles θ .

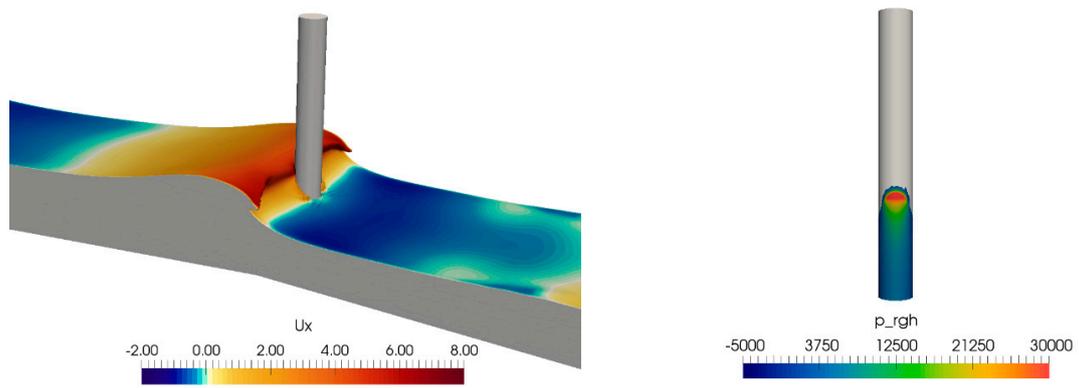

Table 3. The peak value of wave forces in different transverse inclined angles.

Case	Total Horizontal Wave Forces F_T (N)	Low-Order Wave Forces F_L (N)	High-Order Wave Forces F_H (N)
A	11,952	4554	7458
B	8103	4058	4605
C	8793	4459	4962
D	9553	5161	4963
E	14228	6957	8200
F	25,965	13,213	15,016

4.3. The Processes of Breaking Waves past the Cylinder

To explore further the mechanism of breaking waves past the cylinders with different transverse inclined angles, the two typical angles $\theta = 0^\circ$ and 45° are studied. Figure 15 shows the variations of the free surface with the contour plot of horizontal velocity during the interaction between the breaking wave and a vertical cylinder ($\theta = 0^\circ$). Meanwhile, the pressure p_{rgh} on the cylinder is also presented at the corresponding time instants. Before the incident wave reaches the cylinder, the horizontal velocity of the flow field around the cylinder is very low. At this moment, the cylindrical surface is subjected to a minimum pressure, as shown in Figure 15a. With the wave propagating along the slope, the horizontal velocity at the wave crest begins to increase. In Figure 15b, the wave crest almost vertically impacts on the cylinder with high horizontal velocity. The maximum pressure is observed at the corresponding location of the cylinder due to the water velocity reducing to zero in a short time. At the same time, the total horizontal breaking wave force reaches the peak value in Figure 11. The free surface feature corresponding to the second peak of the F_T is shown in Figure 15c. As pointed out by Kamath et al. [11], the second peak of wave force plot results from the trailing water mass impacting the cylinder. A chute-like jet produced behind the cylinder is also observed. In Figure 15d, the horizontal breaking wave force on the cylinder drops to a very small value when the wave travels past the cylinder.

Figure 16 shows the free surface deformation and horizontal velocity contours around the cylinder placed with $\theta = 45^\circ$. Before the incident wave arriving at the cylinder, the horizontal velocity of water mass around the cylinder is small and the pressure on the surface of the cylinder is not evident, as shown in Figure 16a. Subsequently, the overturning wave crest impacts the cylinder and produces the maximum pressure on the cylinder in Figure 16b. However, the peak value of pressure is much less than the peak value of the vertical cylinder. It demonstrates that the interaction between the breaking wave and the inclined cylinder is less severe compared to the vertical cylinder, which is consistent with the prediction as shown in Figure 14. When the cylinder is placed with a transverse inclined angle, the wave reflection is weaker than the vertical cylinder case, which eventually results in the smaller horizontal velocity at the wave crest. Another difference between two typical inclined angles is that the chute-like jet behind the cylinder cannot be observed in Figure 16c. It reinforces the aforementioned that the secondary peak of wave force is disappeared when $\theta = 45^\circ$, as shown in Figure 11.

5. Conclusions and Future Work

In this paper, the open-source CFD toolbox waves2Foam based on Open FOAM is employed to numerically simulate breaking waves past a standing cylinder with different transverse inclined

angle θ . The present numerical results of the free surface elevations and the horizontal breaking wave forces are in good agreement with the published data. The variation of θ has a significant effect on the characteristics of the wave forces and the free surface elevations.

The vertical cylinder ($\theta = 0^\circ$) is subject to the largest normalized horizontal wave force F_T and normalized high-order wave force F_H . The high-order wave force has a large contribution to the total horizontal breaking wave force. The minimum ratio of the normalized high-order wave forces to the normalized total horizontal forces is 51.95% when $\theta = 45^\circ$. Concurrently, the minimum normalized F_H occurs for the case of the cylinder with $\theta = 45^\circ$. The normalized low-order wave force, F_L , slightly decreases as the θ increases. For the free surface elevations in front of the cylinder, the largest value is obtained when the breaking wave past a vertical cylinder and the minimum value is observed for the cylinder with $\theta = 45^\circ$. The secondary load cycle phenomenon is not observed when the cylinder is placed with $\theta = 30^\circ$ and 45° .

In future work, the breaking wave past two cylinders in tandem will be conducted to study the effect of the distance between two cylinders and transverse inclined angles on the forces. Meanwhile, the breaking wave past the structures with different shapes will be also investigated.
