**Abstract:** The ridge–furrow rainwater harvesting (RFRH) planting mode is widely used in arid and semi-arid areas to solve the problems of agricultural water shortage and low productivity. However, the impact of film mulching on the stability of soil carbon pools makes this planting mode vulnerable to the risk of increased soil carbon emissions and carbon pool losses. In order to clarify the relationship between soil carbon emissions and hydrothermal factors, as well as the regulatory effect of biochar application on soil carbon sequestration and reduced emissions under this planting mode, we set up a biochar application experiment. The effects of the biochar application (at 10 Mg ha<sup>-1</sup> biochar and 20 Mg ha<sup>-1</sup> biochar) on the soil water dynamics, soil temperature changes, CO<sub>2</sub>-C and CH<sub>4</sub>-C flux dynamics, grain yield, carbon emission efficiency, and the net ecosystem carbon budget in wheat fields under the RFRH planting mode were investigated, with no biochar application as the control. The results showed that applying biochar increased the soil water content, soil average temperature, cumulative CH<sub>4</sub>-C uptake, wheat grain yield, and carbon emission efficiency by 3.10–12.23%, 0.98–3.53%, 59.27–106.65%, 3.51–16.42%, and 18.52–61.17%, respectively; reduced the cumulative CO<sub>2</sub>-C emissions by 7.51–31.07%; and increased the net ecosystem carbon budget by 2.91 Mg C ha<sup>-1</sup> to 6.06 Mg C ha<sup>-1</sup>. The results obtained by equation fitting showed that in wheat fields under RFRH, the CO<sub>2</sub>-C emission fluxes had negative and positive exponential relationships with the soil water content and soil temperature, respectively, while the CH<sub>4</sub>-C uptake fluxes had no significant correlation with the soil water content and had an inverse U-shaped quadratic function relationship with soil temperature. Overall, these results suggest that the application of biochar to wheat fields under RFRH can improve grain yield, farmland carbon emission efficiency, and the net ecosystem carbon budget, and change wheat fields from a carbon source to a carbon sink. These results can provide a theoretical basis and technical support for efficient, green, and sustainable production in farmland in arid and semi-arid areas.

## 1. Introduction

The global population is expected to reach 9.8 billion by 2050, and food production will need to be increased by 70% to meet the demand due to population growth [1]. It is difficult to increase the area of arable land and it actually tends to decrease, so it is necessary to enhance the productivity of land to increase crop production [2,3]. At present, about 41% of the world's arable land area is distributed in arid and semi-arid areas [4], and many

studies have indicated that there is great potential for improving the productivity of land in these areas [3]. For many years, the main factor that has restricted agricultural production in arid and semi-arid areas is a shortage of water [5]. In order to address this issue, some technical approaches for improved water utilization have been developed. In particular, the ridge–furrow rainwater harvesting (RFRH) planting technique has gradually become an important planting mode for crops in arid and semi-arid areas because it can improve the soil moisture status in the crop root zone, and promote crop growth and yield formation by collecting precipitation via film covering on the ridge [6–9].

Film mulching regulates the soil hydrothermal environment and also changes the stability of the soil carbon pool [10]. Many studies have shown that film mulching promotes the mineralization and decomposition of soil organic carbon and increases losses from the soil organic carbon pool [11–15], thereby affecting the quality of farmland soil and leading to the gradual degradation of farmland [16,17]. In addition, the soil carbon pool is closely related to the atmospheric carbon pool [18,19], so the increased soil carbon emissions under film mulching will increase the atmospheric carbon concentration and exacerbate global warming [20–25]. Therefore, there is an urgent need to sequester carbon and reduce emissions under the RFRH planting mode.

Soil carbon sequestration and carbon emissions are affected by soil hydrothermal factors [26–28]. Adding biochar can regulate the soil temperature and soil water content [26,29], and many studies have also shown that biochar can stabilize the soil carbon pool, reduce the mineralization and decomposition of soil organic carbon [30–32], and increase the storage of soil carbon [29,33–35]. However, previous studies into carbon sequestration and reducing emissions using biochar were mostly conducted in paddy fields in humid areas or incubation experiments in laboratories [32,36–39]. Clearly, the ecological environment, soil quality, and farming measures differ in dry farmland in non-humid areas. However, few studies have investigated the effect of biochar application on soil carbon sequestration in dry farmland and whether the application of biochar can reduce soil carbon emissions under the RFRH planting mode.

Wheat is the food crop with the largest planting area and trade volume in the world [40]. Coupled with the fact that it is used for food up to 65% [41], it has an irreplaceable role in meeting global food demand. Wheat has a wide range of adaptability to environmental conditions [41]. It is also an important cereal crop in dryland regions [42]. Carrying out research on wheat planting is important for both agricultural production in arid and semi-arid areas and global food security.

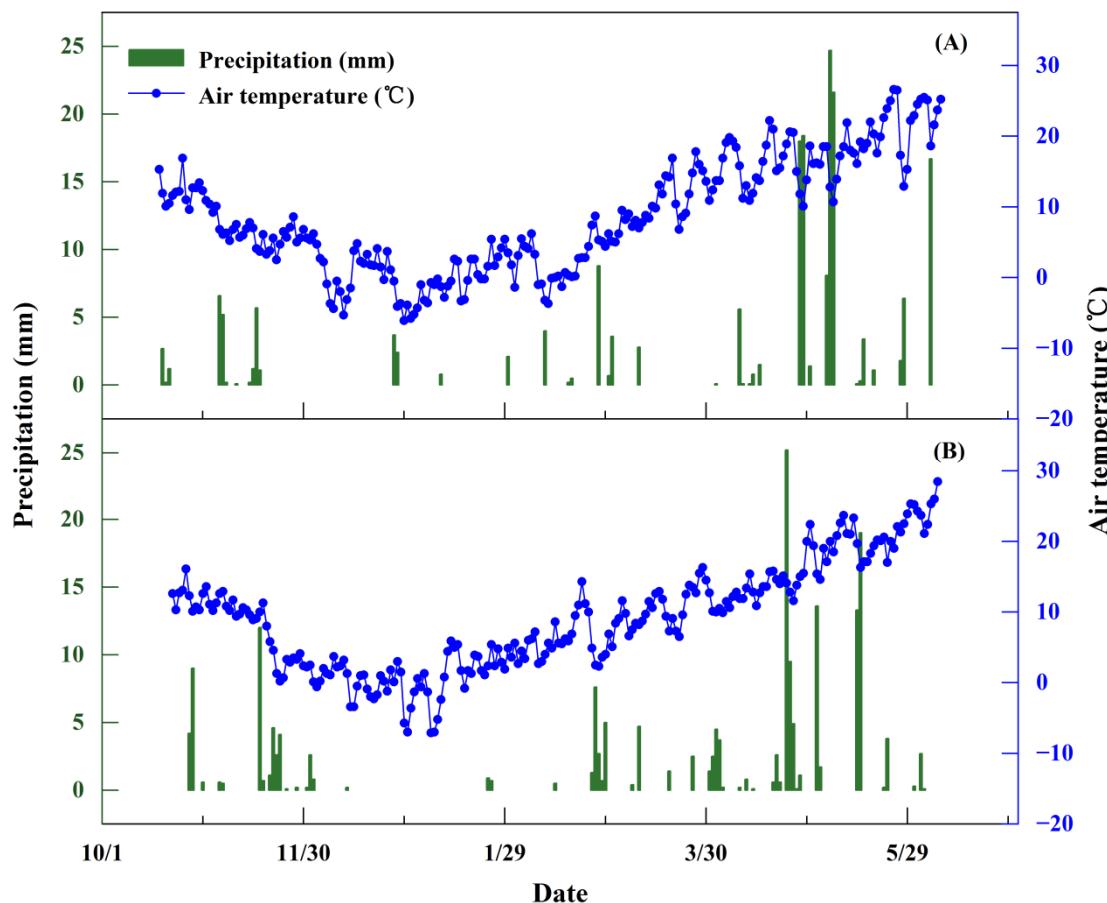

Thus, in the present study, different amounts of biochar were applied under the RFRH planting mode using wheat as the test crop in order to: (1) investigate the effects of biochar application on the soil hydrothermal characteristics and gaseous carbon ( $\text{CO}_2$  and  $\text{CH}_4$ ) emissions, as well as the relationships between carbon emissions and soil hydrothermal factors under RFRH planting; (2) determine the effects of biochar application on the crop yield under RFRH planting; and (3) understand the effects of biochar application on the carbon balance under RFRH planting, and the regulatory effects of biochar application and the associated mechanisms on soil carbon sequestration and reductions in emissions under RFRH planting in a dry farmland environment in a non-humid area. We aimed to identify a suitable technical approach to save water, increase yields, reduce emissions, and facilitate carbon sequestration, thereby providing a theoretical basis for high-quality production on farmland in arid and semi-arid areas.

## 2. Materials and Methods

### 2.1. Experimental Site Situation and Biochar Characterization

The experiment was conducted at Yangling Experimental Station ( $108^{\circ}04' \text{ E}$ ,  $34^{\circ}17' \text{ N}$ ), Institute of Water-saving Agriculture in Arid Areas of China, which is located at an altitude of 506 m. The meteorological data were obtained based on a 30-year average from the Yangling Weather Station, which is about 200 m away from the experimental field. At the experimental site, the annual average temperature is  $13.0^{\circ}\text{C}$ , the annual number of

sunshine hours is 2196 h, and the frost-free period is 220 days. The precipitation is generally low with an uneven distribution in this region. The annual average precipitation was about 600 mm, the annual average evaporation was about 933.2 mm, and the average precipitation during the growth period of winter wheat was about 200 mm. The detailed precipitation and air temperature data during the experiment were also obtained from this weather station, as shown in Figure 1. The soil in the experimental field is Lou soil, which belongs to Eum-Orthic Anthrosols. Before the experiment, the basic properties of the soil in the top 0–20 cm layer were as follows: pH = 7.59, bulk density = 1.25 g cm<sup>-3</sup>, soil organic matter = 13.22 g kg<sup>-1</sup>, total nitrogen = 0.94 g kg<sup>-1</sup>, available nitrogen (nitrate nitrogen and ammonium nitrogen) = 48.62 mg kg<sup>-1</sup>, available phosphorus = 11.10 mg kg<sup>-1</sup>, and available potassium = 110.69 mg kg<sup>-1</sup>.

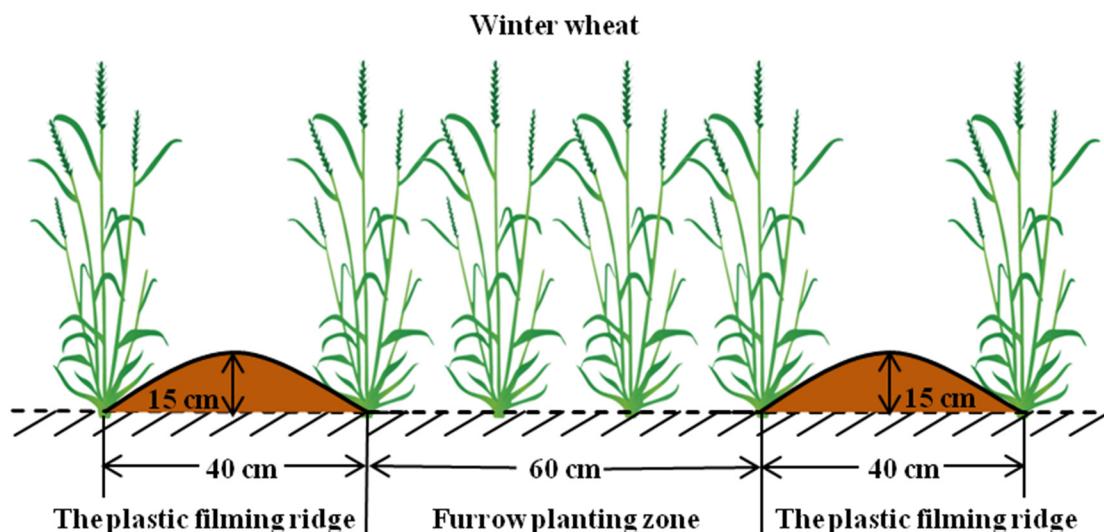

**Figure 1.** Precipitation and air temperature distributions during the winter wheat growing seasons in 2018–2019 (A) and 2020–2021 (B).

The biochar used in the experiment was purchased from Zedi Agricultural Science and Technology Company (Jiangsu, China). It was produced with the anaerobic pyrolysis of equal weight rice straw and rice husk at 500 °C for 2 h. The properties of biochar were as follows: pH = 9.27, total N = 6.5 g kg<sup>-1</sup>, total C = 205.6 g kg<sup>-1</sup>, total P = 11.34 g kg<sup>-1</sup>, total K = 17.42 g kg<sup>-1</sup>, cation exchange capacity = 16.2 cmol kg<sup>-1</sup>, specific surface area = 29.6 m<sup>2</sup> g<sup>-1</sup>, and bulk density = 0.35 g cm<sup>-3</sup>.

## 2.2. Experimental Design and Field Management

A single factor randomized block design was employed with three blocks and the following three treatments: (1) no biochar application (B0) as the control; (2) application of biochar at 10 Mg ha<sup>-1</sup> (B10); and (3) application of biochar at 20 Mg ha<sup>-1</sup> (B20). Both the biochar and fertilizer were applied basally before sowing. The amounts of fertilizer applied

under each treatment were the same with  $225 \text{ kg ha}^{-1}$  pure N,  $75 \text{ kg ha}^{-1}$   $\text{P}_2\text{O}_5$ , and  $150 \text{ kg ha}^{-1}$   $\text{K}_2\text{O}$ . The main local wheat cultivar Xinong 979 was used as the test material. Wheat was sown manually in strips around October 20 each year at a rate of 2.25 million plants  $\text{ha}^{-1}$  with a row spacing of 20 cm, and it was harvested during early June in the following year without replanting after harvest. The RFRH planting mode was used for all of the treatments (Figure 2), where the widths of the furrows and ridges were 60 cm and 40 cm, respectively. The 15 cm-high ridges were covered with plastic film to collect precipitation and wheat was planted in the furrows. Other management measures applied in the experimental field were the same as those used for wheat production in local fields and they were consistent across treatments.

**Figure 2.** Schematic diagram of the ridge–furrow rainwater harvesting (RFRH) planting mode.

### 2.3. Sampling and Measurement Methods

#### 2.3.1. $\text{CO}_2$ and $\text{CH}_4$ Emission Measurement

The  $\text{CO}_2$  and  $\text{CH}_4$  emissions in the field were measured by static chamber-gas chromatography. The static chamber comprised a base ( $40 \text{ cm} \times 30 \text{ cm} \times 15 \text{ cm}$ ) and top box ( $40 \text{ cm} \times 30 \text{ cm} \times 40 \text{ cm}$ ). The base was made of stainless steel and it was sealed by a water-filled groove at the top. The top box was made of polyvinyl chloride sheet and it was wrapped with a layer of heat-insulating reflective material on the outside. A thermometer was placed at the top and a gas sampling pipe in the middle. The long side of the base was perpendicular to the planting row and it was positioned according to the proportion of each part of the planting pattern. Sampling commenced after fertilization and sowing, and it was conducted every half a month until the wheat was harvested. Sampling was always performed at 9:00–11:00 a.m. During sampling, the top box was fastened to the base and sealed with water. Gas samples were then extracted at intervals of 0, 10, 20, and 30 min using 50-mL syringes, and the temperature in the box was recorded. After sampling, the gas samples were analyzed as soon as possible using a GC-2010 Plus gas chromatograph (Shimadzu, Kyoto, Japan) with a flame ionization detector. The gas chromatograph was calibrated with standard gas before each test. The  $\text{CO}_2$  and  $\text{CH}_4$  emission fluxes were calculated by the following formula [43]:

$$F = k \times (273.15/T) \times (V/A) \times (\Delta c/\Delta t) \quad (1)$$

where  $F$  is the gas emission flux ( $\text{mg CO}_2\text{-C m}^{-2} \text{ h}^{-1}$  or  $\mu\text{g CH}_4\text{-C m}^{-2} \text{ h}^{-1}$ ),  $k$  is the conversion factor ( $0.536 \text{ kg C m}^{-3}$  for both  $\text{CO}_2$  and  $\text{CH}_4$ ),  $T$  is the average temperature inside the box during sampling (K),  $V$  is the volume of the sampling box ( $\text{m}^3$ ),  $A$  is the area of the bottom of the sampling box ( $\text{m}^2$ ), and  $\Delta c/\Delta t$  is the rate of change in the

gas concentration in the sampling box per unit time ( $\text{CO}_2$ : ppm  $\text{h}^{-1}$ ;  $\text{CH}_4$ : ppb  $\text{h}^{-1}$ ). Linear regressions were performed based on the gas concentration and sampling time, and flux values were accepted when  $r^2 > 0.90$ . Cumulative gas emissions were estimated by integrating the monthly average fluxes during the wheat growing season [44].

### 2.3.2. Soil Water Content and Soil Temperature

When the gas samples were collected, the volumetric water content of the 0–20 cm soil layer was measured using an AZS-100 TDR portable soil moisture meter (IMKO, Ettlingen, Germany) and converted into the soil mass water content based on the soil bulk density. The soil temperature at a depth of 10 cm was also measured with a geothermometer at the same time.

### 2.3.3. Wheat Yield, Aboveground Biomass, and Carbon Emission Efficiency (CEE)

At maturity, 1 m × 1 m sample plots (including the rainwater harvesting ridge and planting furrow areas) were harvested manually. The aboveground biomass weight, spike number, and kernel number per spike were measured after drying, before threshing to measure the yield and 1000-grain weight. The yield per hectare, spike number per hectare, and aboveground biomass per hectare were then calculated. The CEE was calculated based on the wheat yield and total gaseous carbon emissions (TGCE) by the following formula [45]:

$$\text{CEE} = \text{WY}/\text{TGCE} \quad (2)$$

where WY is the wheat yield ( $\text{Mg ha}^{-1}$ ), and TGCE denotes the total gaseous carbon ( $\text{CO}_2\text{-C}$  and  $\text{CH}_4\text{-C}$ ) emissions during the wheat growing season ( $\text{Mg ha}^{-1}$ ).

### 2.3.4. Net Ecosystem Carbon Budget (NECB)

The NECB was estimated for a wheat field by the following formula [46]:

$$\text{NECB} = \text{GPP} - \text{CO}_2\text{-C} - \text{Harvest-C} - \text{CH}_4\text{-C} + \text{Add-C} \quad (3)$$

where  $\text{CO}_2\text{-C}$  and  $\text{CH}_4\text{-C}$  are the cumulative  $\text{CO}_2$  and  $\text{CH}_4$  carbon emissions from farmland during the wheat growing season, respectively ( $\text{Mg ha}^{-1}$ ), Harvest-C is the amount of carbon contained in the harvested aboveground biomass ( $\text{Mg ha}^{-1}$ ), Add-C is the amount of carbon added ( $\text{Mg ha}^{-1}$ ), and GPP is the gross primary production ( $\text{Mg ha}^{-1}$ ), which was extrapolated from the net primary production (NPP) based on the carbon use efficiency (carbon use efficiency = NPP/GPP) [47]. The carbon use efficiency of wheat was estimated as 0.65 [48–50].

The NPP of a wheat field was estimated by the following formula [51]:

$$\text{NPP} = \text{NPP}_{\text{shoot}} + \text{NPP}_{\text{root}} + \text{NPP}_{\text{litter}} + \text{NPP}_{\text{rhizodeposit}} \quad (4)$$

where  $\text{NPP}_{\text{shoot}}$ ,  $\text{NPP}_{\text{root}}$ ,  $\text{NPP}_{\text{litter}}$ , and  $\text{NPP}_{\text{rhizodeposit}}$  are the NPP values corresponding to shoot, root, litter, and rhizodeposit, respectively. Shoot was the harvested aboveground biomass and the other parts were estimated as described by Huang et al. [52] using allometric relationships. The root/shoot ratio was taken as 0.11 [52]. Litter accounted for about 5% of the shoot and root biomass [53,54]. Rhizodeposit accounted for about 10% of the shoot and root biomass [55]. The carbon content of each part was treated as 400 g  $\text{kg}^{-1}$  [56].

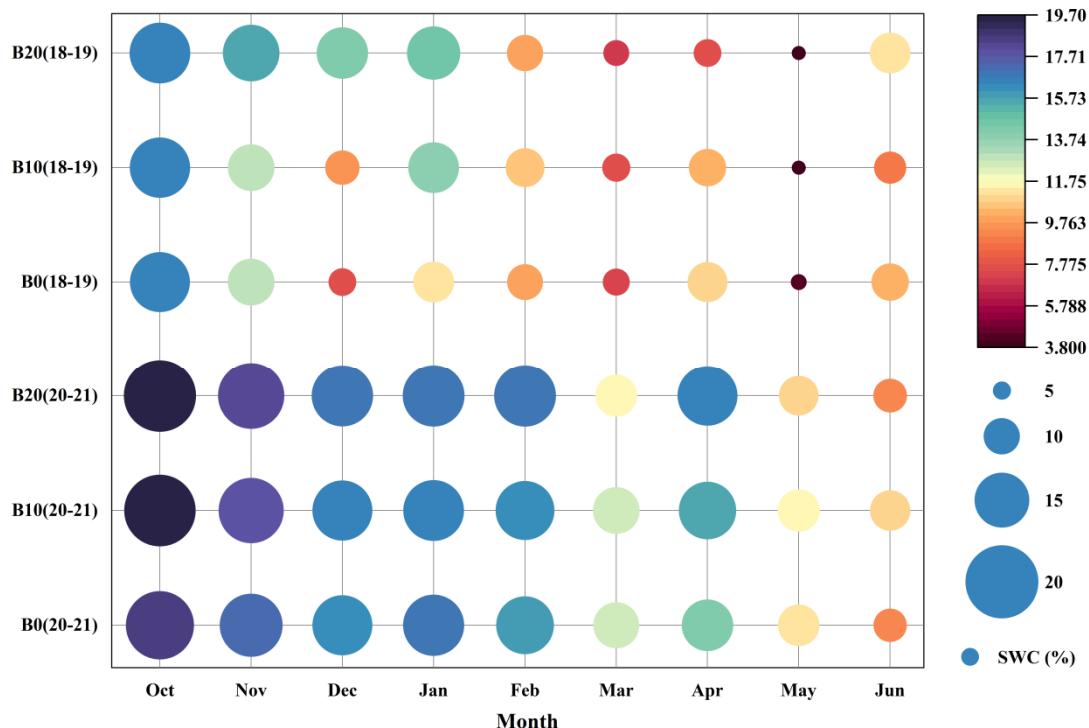

## 2.4. Statistical Analysis

Statistical analyses were carried out on the data from 2018–2019 and 2020–2021 (the data from 2019–2020 were not successfully obtained due to the epidemic). Data entry and sorting were conducted using Microsoft Excel 2007. Analysis of variance was performed using IBM SPSS Statistics 20. Equations representing the relationships between gas emissions and hydrothermal factors were fitted using IBM SPSS Statistics 20. The figures were prepared using OriginPro 2022.

### 3. Results

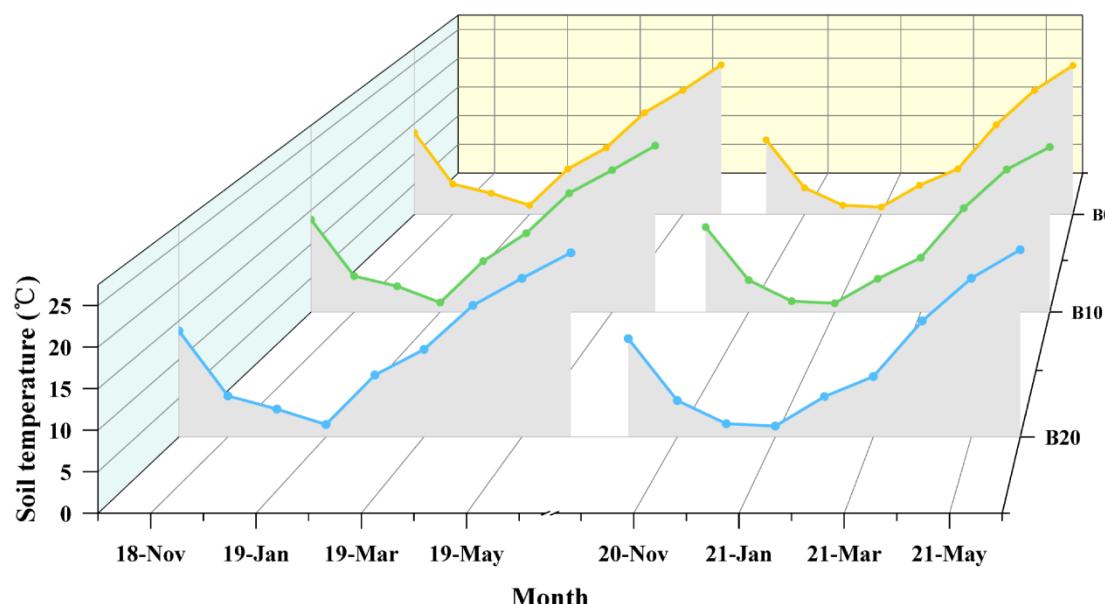

#### 3.1. Soil Water Content and Soil Temperature

The soil water contents in the 0–20 cm soil layer tended to decrease during the wheat growth process. The application of biochar affected soil water content. With B0 as the control, the increasing range of soil water content in different months varied from −14.06% to 25.18% and from −30.66% to 85.26% under B10 and B20, respectively (Figure 3). Finally, the application of biochar significantly increased the average soil water content during the wheat growth period ( $p < 0.05$ ). Compared with B0, the average soil water contents were 3.10–5.64% and 3.24–12.23% higher under B10 and B20, respectively (Figure 3).

**Figure 3.** Changes in soil water content in the 0–20 cm soil layer under different amounts of added biochar during the winter wheat growing seasons in 2018–2019 and 2020–2021. Note: SWC represents soil water content. Both the size and color of the circle represent the level of soil water content. B20, B10, and B0 represent 20, 10, and 0 Mg biochar  $\text{ha}^{-1}$ , respectively.

The soil temperature at a depth of 10 cm decreased initially and then increased under each treatment during the wheat growth process, with a trough period in December–January (Figure 4). The application of biochar affected soil temperature. With B0 as the control, the increasing range of soil temperature in different months varied from −6.67% to 8.57% and from −3.64% to 16.67% under B10 and B20, respectively (Figure 4). Overall, the application of biochar reduced the variations in the soil temperature range to some extent and increased the average soil temperature during the wheat growth period. Compared with B0, the average soil temperatures were 1.96–3.53% and 0.98–2.35% higher under B10 and B20, respectively (Figure 4).

**Figure 4.** Changes in soil temperature at a depth of 10 cm under different amounts of added biochar during the winter wheat growing seasons in 2018–2019 and 2020–2021.

### 3.2. Carbon Emissions

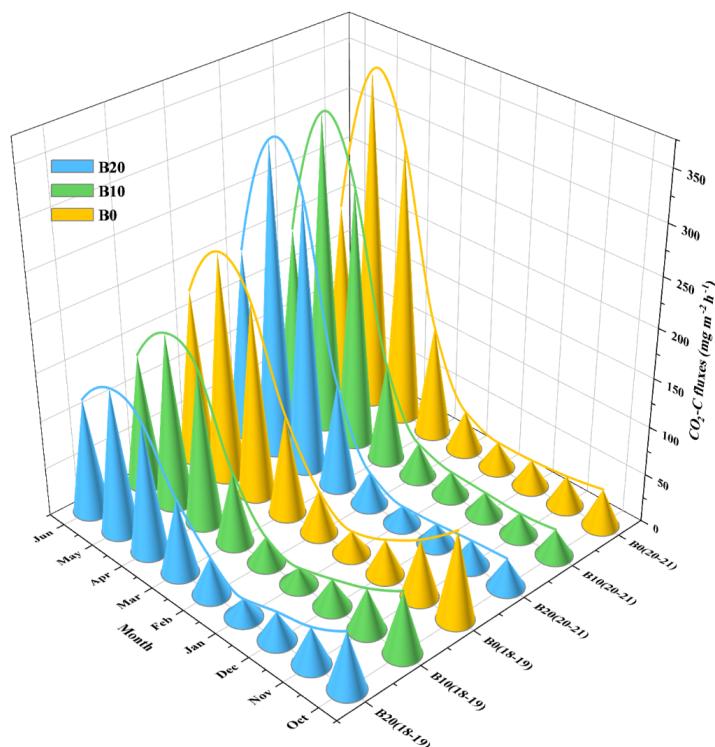

#### 3.2.1. CO<sub>2</sub>-C Emissions

The CO<sub>2</sub>-C emission fluxes under different treatments exhibited similar seasonal variations, where they all decreased initially, before increasing and finally decreasing, with the peak occurring in May (wheat filling stage) (Figure 5). The application of biochar affected the CO<sub>2</sub>-C emission fluxes in wheat fields. With B0 as the control, the decreasing range of the CO<sub>2</sub>-C emission fluxes in different months varied from 0.48% to 39.38% and from −0.55% to 35.99% under B10 and B20, respectively (Figure 5). In general, the CO<sub>2</sub>-C emission fluxes were significantly higher under B0 than B10 and B20 during the same period ( $p < 0.05$ ). Compared with B0, the average CO<sub>2</sub>-C emission fluxes were 8.54–24.64% and 7.51–31.07% lower under B10 and B20, respectively (Figure 5).

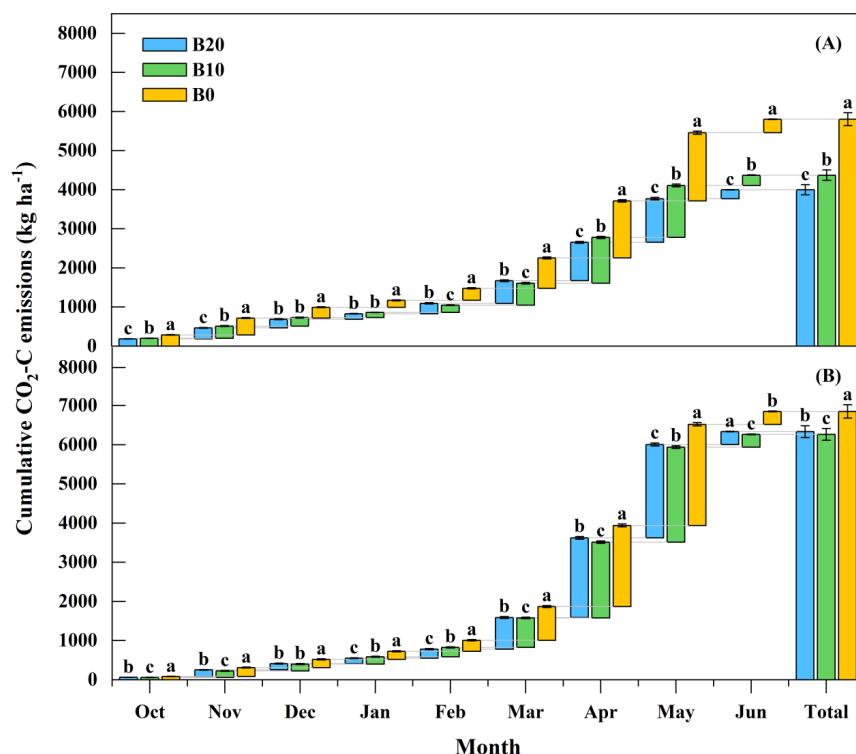

As shown in Figure 6, March–May was the key stage for soil CO<sub>2</sub>-C emissions from wheat fields, and the cumulative CO<sub>2</sub>-C emissions in this stage accounted for 66.94–82.47% of the cumulative CO<sub>2</sub>-C emissions in the whole wheat growing season. The application of biochar significantly reduced the cumulative CO<sub>2</sub>-C emissions from wheat fields ( $p < 0.05$ ). Compared with B0, the cumulative CO<sub>2</sub>-C emissions were 584.83–1429.88 kg ha<sup>−1</sup> and 514.18–1802.82 kg ha<sup>−1</sup> lower under B10 and B20, respectively (Figure 6).

#### 3.2.2. CH<sub>4</sub>-C Uptake

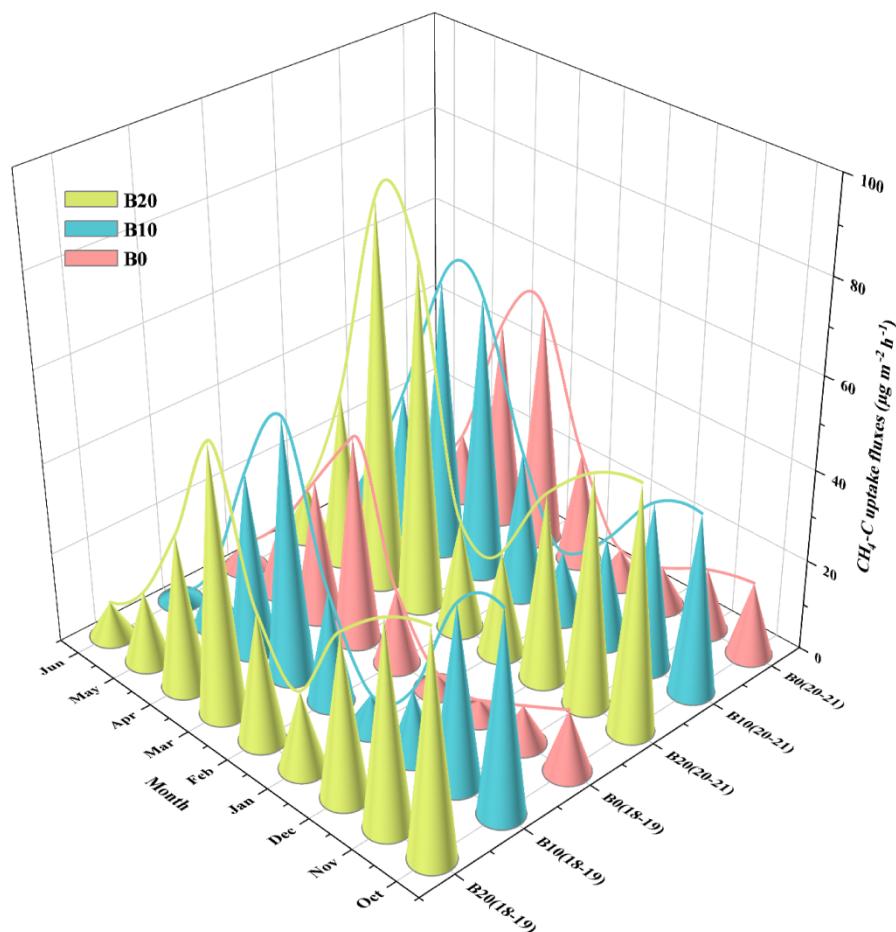

As shown in Figure 7, the CH<sub>4</sub>-C uptake fluxes under different treatments all decreased initially, before increasing and finally decreasing. The application of biochar affected the CH<sub>4</sub>-C uptake fluxes in wheat fields. With B0 as the control, the increasing range of the CH<sub>4</sub>-C uptake fluxes in different months varied from −50.00% to 370.42% and from −1.86% to 967.86% under B10 and B20, respectively (Figure 7). In general, the CH<sub>4</sub>-C uptake fluxes were significantly lower under B0 than B10 and B20 during the same period ( $p < 0.05$ ). Compared with B0, the average CH<sub>4</sub>-C uptake fluxes were 59.29–65.09% and 97.93–106.68% higher under B10 and B20, respectively (Figure 7).

**Figure 5.** Variations in field CO<sub>2</sub>-C emission fluxes under different amounts of added biochar during the winter wheat growing seasons in 2018–2019 and 2020–2021. Note: The circular cone height represents the CO<sub>2</sub>-C flux value, and the Akima spline curve represents the trend of CO<sub>2</sub>-C fluxes with time.

**Figure 6.** Cumulative CO<sub>2</sub>-C emissions under different amounts of added biochar during the winter wheat growing seasons in 2018–2019 (A) and 2020–2021 (B). Note: The column length represents the mean  $\pm$  standard error of newly added cumulative CO<sub>2</sub>-C emissions in each stage, and different lowercase letters indicate significant differences between treatments (Duncan's test,  $p < 0.05$ ).

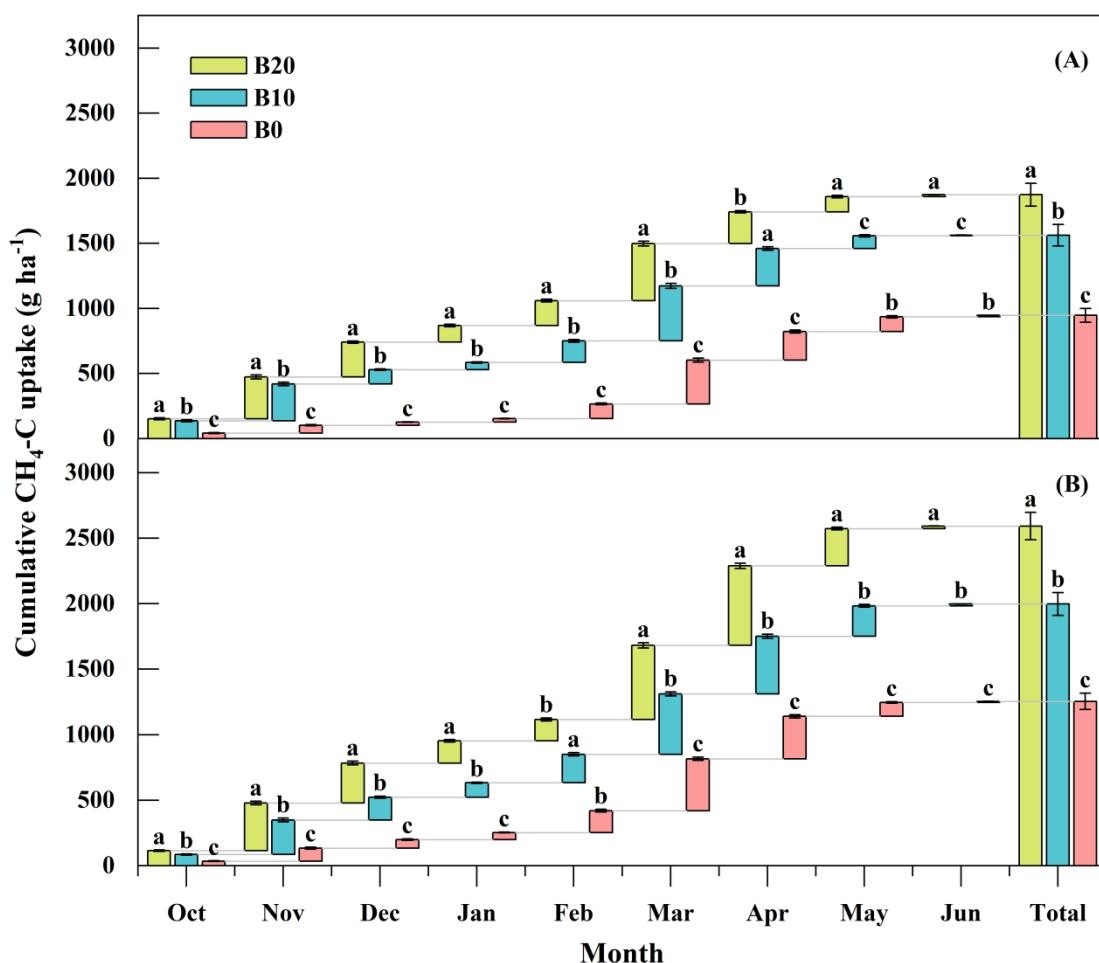

**Figure 7.** Variations in field CH<sub>4</sub>-C uptake fluxes under different amounts of added biochar during the winter wheat growing seasons in 2018–2019 and 2020–2021. Note: The circular cone height represents the CH<sub>4</sub>-C uptake flux value, and the Akima spline curve represents the trend of CH<sub>4</sub>-C uptake fluxes with time.

As shown in Figure 8, March–April was the active stage for soil CH<sub>4</sub>-C uptake in wheat fields, and the cumulative CH<sub>4</sub>-C uptake in this stage accounted for 36.40–58.75% of the cumulative CH<sub>4</sub>-C uptake in the whole wheat growing season. The cumulative CH<sub>4</sub>-C uptake tended to increase as the biochar application amount increased. Compared with B0, the cumulative CH<sub>4</sub>-C uptake amounts were 616.24–743.44 g ha<sup>-1</sup> and 926.72–1337.69 g ha<sup>-1</sup> higher under B10 and B20, respectively (Figure 8).

### 3.3. Relationships between Carbon Emissions and Hydrothermal Factors

The relationships between the CO<sub>2</sub>-C emission fluxes and soil water contents under different biochar application amounts all conformed to an exponential decay equation. According to the fitted equations, the soil water content could explain 21.1–34.3% of the variations in the CO<sub>2</sub>-C emission fluxes. The coefficient of determination ( $R^2$ ) for the fitted equation increased as the amount of added biochar increased (Table 1). However, the relationships between the CO<sub>2</sub>-C emission fluxes and soil temperature under different treatments all conformed to an exponential growth equation. According to the fitted equations, soil temperature could explain 72.6–75.8% of the variations in the CO<sub>2</sub>-C emission fluxes. The  $R^2$  value for the fitted equation decreased as the amount of added biochar increased (Table 1).

**Figure 8.** Cumulative  $\text{CH}_4\text{-C}$  uptake under different amounts of added biochar during the winter wheat growing seasons in 2018–2019 (A) and 2020–2021 (B). Note: The column length represents the mean  $\pm$  standard error of newly added cumulative  $\text{CH}_4\text{-C}$  uptake in each stage, and different lowercase letters indicate significant differences between treatments (Duncan's test,  $p < 0.05$ ).

**Table 1.** Equations of the relationships between the  $\text{CO}_2\text{-C}$  emission fluxes ( $F$ ) and soil water content (SWC) and soil temperature (ST) under different amounts of added biochar in wheat fields.

Equation	Treatment	a	b	$R^2$	p
$F = a \times e^{(b \times \text{SWC})}$	B20	320.212	-0.124	0.343	0.011
	B10	276.467	-0.115	0.235	0.042
	B0	294.764	-0.106	0.211	0.055
$F = a \times e^{(b \times \text{ST})}$	B20	20.019	0.103	0.726	0.000
	B10	19.963	0.104	0.745	0.000
	B0	27.301	0.099	0.758	0.000

Note: B20, B10, and B0 represent 20, 10, and 0  $\text{Mg biochar ha}^{-1}$ , respectively.

There was no significant correlation between the  $\text{CH}_4\text{-C}$  uptake flux and soil water content under each treatment (Table 2). However, the relationships between the  $\text{CH}_4\text{-C}$  uptake fluxes and soil temperatures under different biochar application amounts all conformed to an inverse U-shaped quadratic equation. According to the fitted equations, the soil temperature could explain 46.3–72.6% of the variations in the  $\text{CH}_4\text{-C}$  uptake flux. The application of biochar increased the  $R^2$  value for the fitted equation (Table 2).

**Table 2.** Equations of the relationships between the CH<sub>4</sub>-C uptake fluxes (F) and soil water content (SWC) and soil temperature (ST) under different amounts of added biochar in wheat fields.

Equation	Treatment	a	b	c	R <sup>2</sup>	p
F = a × SWC + b	B20	1.417	19.861	-	0.087	0.234
	B10	1.183	15.479	-	0.069	0.293
	B0	-0.099	19.587	-	0.001	0.920
F = a × ST <sup>2</sup> + b × ST + c	B20	-0.317	7.317	14.414	0.552	0.002
	B10	-0.310	7.604	3.228	0.726	0.000
	B0	-0.202	5.167	-1.793	0.463	0.009

Note: B20, B10, and B0 represent 20, 10, and 0 Mg biochar ha<sup>-1</sup>, respectively.

### 3.4. Wheat Yield, TGCE, and CEE

The spike numbers per hectare, kernel number per spike, and 1000-grain weights all increased as the amount of added biochar increased. Compared with B0, the spike numbers per hectare, kernel number per spike, and 1000-grain weights were 0.91–2.21% and 4.64–4.87%, 1.12–4.73% and 2.27–7.97%, and 0.39–1.78% and 0.58–2.72% higher under B10 and B20, respectively (Table 3). Thus, the wheat yields also increased as the amount of added biochar increased. Compared with B0, the wheat yields were 3.51–8.82% and 10.68–16.42% higher under B10 and B20, respectively (Figure 9A). In addition, the application of biochar significantly reduced the TGCE values in wheat fields (*p* < 0.05). Compared with B0, the TGCE values were 8.55–24.66% and 7.53–31.09% lower under B10 and B20, respectively (Figure 9B). Therefore, the application of biochar significantly improved the CEE values (*p* < 0.05). Compared with B0, the CEE values were 18.52–37.86% and 25.93–61.17% higher under B10 and B20, respectively (Figure 9C).

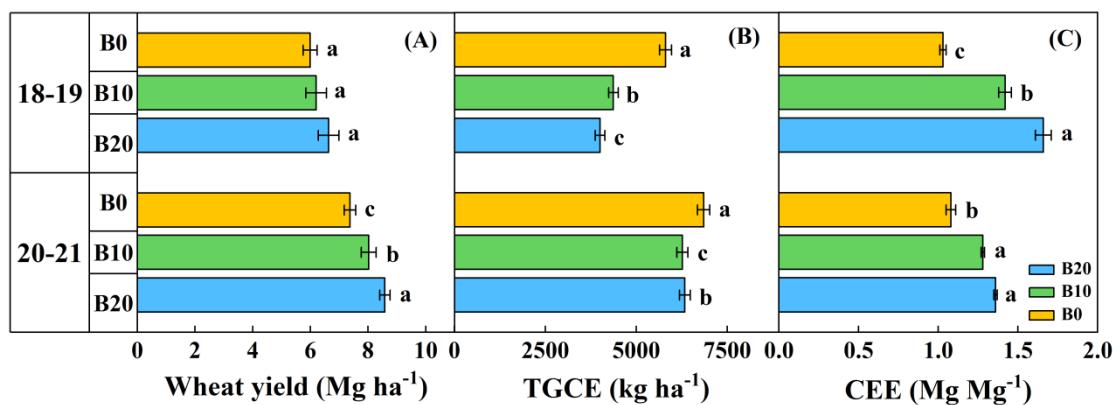

**Table 3.** Wheat yield components under different amounts of added biochar in 2018–2019 and 2020–2021.

Year	Treatment	Spike Number ha <sup>-1</sup> ( $\times 10^4$ )	Kernel Number per Spike	1000-Grain Weight (g)
18–19	B0	328.33 (6.98) <sup>b</sup>	40.97 (0.35) <sup>b</sup>	46.57 (0.71) <sup>a</sup>
	B10	331.33 (8.51) <sup>b</sup>	41.43 (0.24) <sup>ab</sup>	46.75 (0.77) <sup>a</sup>
	B20	344.33 (7.36) <sup>a</sup>	41.90 (0.47) <sup>a</sup>	46.84 (0.72) <sup>a</sup>
20–21	B0	453.00 (2.31) <sup>b</sup>	40.17 (0.41) <sup>c</sup>	42.23 (0.28) <sup>b</sup>
	B10	463.00 (2.89) <sup>ab</sup>	42.07 (0.12) <sup>b</sup>	42.98 (0.32) <sup>ab</sup>
	B20	474.00 (6.81) <sup>a</sup>	43.37 (0.34) <sup>a</sup>	43.38 (0.33) <sup>a</sup>

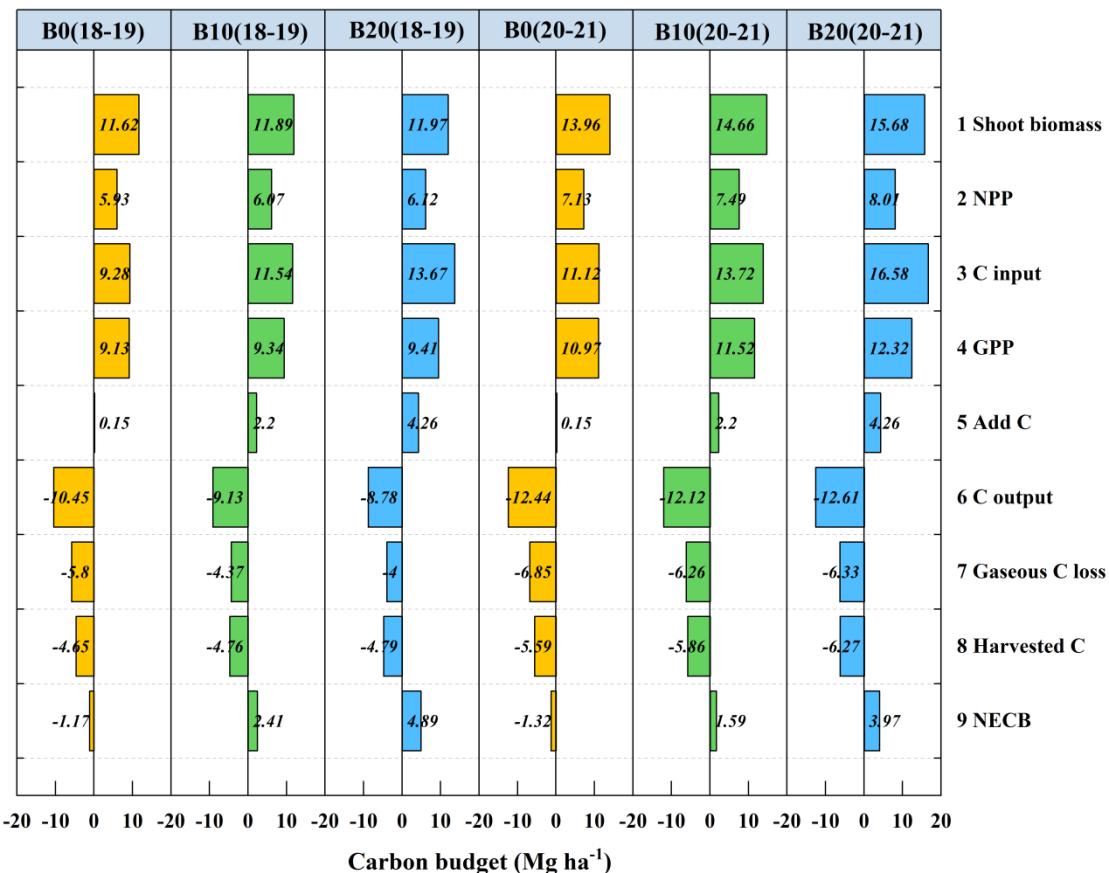

Note: B0, B10, and B20 represent 0, 10, and 20 Mg biochar ha<sup>-1</sup>, respectively. Data are means and (standard errors). Different lowercase letters indicate significant differences between treatment means (Duncan's test, *p* < 0.05).

### 3.5. NECB

The application of biochar significantly increased the C inputs in wheat fields (*p* < 0.05). Compared with B0, the C inputs were 23.38–24.35% and 47.31–49.10% higher under B10 and B20, respectively (Figure 10). Thus, the application of biochar significantly increased the NECB values in wheat fields (*p* < 0.05). Compared with B0, the NECB values were 2.91–3.58 Mg C ha<sup>-1</sup> and 5.29–6.06 Mg C ha<sup>-1</sup> higher under B10 and B20, respectively (Figure 10).

**Figure 9.** Wheat yield (A), total gaseous carbon emissions (B), and carbon emission efficiency (C) under different amounts of added biochar in 2018–2019 and 2020–2021. Note: TGCE represents total gaseous carbon emissions and CEE represents carbon emission efficiency. Values represent means  $\pm$  standard errors and different lowercase letters indicate significant differences between treatments (Duncan's test,  $p < 0.05$ ).

**Figure 10.** Characteristics of net ecosystem carbon budget in winter wheat fields under different amounts of added biochar in 2018–2019 and 2020–2021. Note: NPP represents net primary production, GPP represents gross primary production, and NECB represents net ecosystem carbon budget.

#### 4. Discussion

##### 4.1. Responses of Soil Hydrothermal Characteristics and Carbon Emissions to Biochar Application

The soil water content and soil temperature are important physical characteristics of soil, and they are affected by many factors such as climate, topography, and agronomic measures. Biochar has many hydrophilic functional groups, a large specific surface area,

and high porosity, which contribute to improved soil water retention [57,58]. Studies have shown that the application of biochar can increase the soil water content in farmland [59,60]. Similar to previous studies, the results obtained in the present study showed that the application of biochar significantly increased the soil water content in wheat fields. In addition, Feng et al. [61] found that the application of biochar could increase the soil temperature, and suggested that this may have been related to the effect of biochar on promoting the absorption of solar radiation by the soil. Furthermore, Zhang et al. [62] showed that the application of biochar reduced the variations in the soil temperature range. Moreover, Liu et al. [63] found that biochar changed the soil thermal properties by increasing the total soil porosity, which may have reduced the fluctuations in the soil temperature. Similar to previous studies, we found that the application of biochar increased the average soil temperature during the wheat growth period and reduced the fluctuations in the soil temperature.

The emission of CO<sub>2</sub> from the soil is an important pathway that allows carbon to flow from the soil carbon pool to the atmospheric carbon pool, and these emissions are affected by the physical and chemical properties of soil and biological processes. Biochar can inhibit the mineralization of soil organic carbon by adsorbing soluble organic carbon and promoting the formation of agglomerations [64]. In addition, biochar can slow down the decomposition of soil carbon by inhibiting the activity of glucosidase and microbial growth [65–67]. Lentz et al. [68] conducted biochar application trials in irrigated farmland and showed that the application of 22.4 Mg ha<sup>-1</sup> biochar significantly reduced soil CO<sub>2</sub> emissions by 20%. Similarly, Ge et al. [69] found that the application of biochar in a subtropical bamboo forest reduced cumulative CO<sub>2</sub> emissions. Similar to most previous studies, we found that the application of biochar significantly reduced cumulative CO<sub>2</sub>-C emissions by 7.51–31.07% in wheat fields.

The emission (or uptake) of soil CH<sub>4</sub> is determined by CH<sub>4</sub> production and oxidation processes, which are mainly regulated by methanogenic bacteria and methane-oxidizing bacteria [70]. Biochar application can increase the abundance of methane-oxidizing bacteria and reduce the ratio of methanogenic bacteria relative to methane-oxidizing bacteria, which is conducive to the CH<sub>4</sub> oxidation process [70,71]. Qin et al. [37] showed that the application of biochar could significantly reduce CH<sub>4</sub> emissions from rice fields. Similarly, Karhu et al. [72] demonstrated that the application of 9 Mg ha<sup>-1</sup> biochar increased the CH<sub>4</sub> uptake amount by 96%. Furthermore, Huang et al. [73] found that the *pmoA* gene copy number as an indicator of methane-oxidizing bacteria increased as the biochar application amount increased, which further contributed to accelerated CH<sub>4</sub> oxidation in the soil [74]. Similar to previous studies, the results obtained in the present study demonstrated that the application of biochar significantly increased the cumulative CH<sub>4</sub>-C uptake by 59.27–106.65% in wheat fields, and the cumulative CH<sub>4</sub>-C uptake increased as the amount of added biochar increased.

#### 4.2. Relationships between Carbon Emissions and Hydrothermal Factors

The soil water content and soil temperature are important factors that affect soil CO<sub>2</sub> emissions [27]. Tang et al. [29] found that the CO<sub>2</sub> emission fluxes tended to decrease as the soil water content increased in tobacco fields, and indicated that the CO<sub>2</sub> diffusion resistance was large when the soil water content was high, which was not conducive to CO<sub>2</sub> emissions. Furthermore, Lu et al. [75] showed that the relationship between the CO<sub>2</sub> emission flux and soil water content conformed to an exponential decay equation in the maize growing season, and the R<sup>2</sup> value for the fitted equation increased as the biochar application amount increased. Similar to previous studies, we found that the relationships between the CO<sub>2</sub>-C emission fluxes and soil water contents under different treatments all conformed to an exponential decay equation, and the goodness of fit of the equation increased as the amount of added biochar increased. However, increases in the soil temperature can promote microbial metabolism and the decomposition of organic carbon in soils [76,77], which will increase soil CO<sub>2</sub> emissions. Thus, He et al. [26] showed

that the CO<sub>2</sub> emission flux increased exponentially as the soil temperature increased in a wheat–maize rotation system. Furthermore, Shen et al. [78] showed that the goodness of fit of the equation for the relationship between the CO<sub>2</sub> emission flux and soil temperature decreased after applying biochar. Similar to most previous studies, we found that the relationships between the CO<sub>2</sub>-C emission fluxes and soil temperatures under different biochar application amounts all conformed to an exponential growth equation, and the R<sup>2</sup> values for the fitted equation decreased as the amount of added biochar increased.

The soil water content and soil temperature are also important factors that affect soil CH<sub>4</sub> emissions (or uptake) [79,80]. The relationship between the soil water content and CH<sub>4</sub> emission varies under different soil water conditions, where an increase in the soil water content from a low level can enhance the microbial activity and increase CH<sub>4</sub> uptake [81], whereas a decrease in the soil water content from a high level will make the environment less anaerobic and reduce CH<sub>4</sub> emissions [82]. However, there is no significant correlation between the CH<sub>4</sub> uptake flux and soil water content when the soil water content is in a moderate range with little fluctuation [27,83]. In the present study, the soil water content was moderate range under the different treatments, so we found no significant correlation between the CH<sub>4</sub>-C uptake flux and soil water content under each treatment. In addition, methanogenic bacteria and methane-oxidizing bacteria differ in terms of their preferred temperature ranges and sensitivity to temperature [84,85], and thus the effects of variations in the soil temperature on CH<sub>4</sub> emissions are relatively complex. In particular, Wang et al. [86] found that the relationship between the CH<sub>4</sub> emission flux and soil temperature in a desert steppe soil conformed to a U-shaped quadratic equation. Furthermore, Lu et al. [83] showed that the goodness of fit of the equation for the relationship between the CH<sub>4</sub> uptake flux and soil temperature increased after applying biochar. Similar to previous studies, we found that the relationships between the CH<sub>4</sub>-C uptake fluxes and soil temperatures under different treatments all conformed to an inverse U-shaped quadratic equation, and the R<sup>2</sup> value for the fitted equation increased after applying biochar.

#### 4.3. Responses of Crop Yield and Farmland Carbon Sequestration to Biochar Application

Crop yields have always been a major focus of agricultural research and they cannot be increased without improving the soil environment and crop traits. The application of biochar can increase soil enzyme activity levels [87], soil nutrient supply [88,89], and soil water and fertilizer storage capacity [90,91] to create good soil conditions for crop growth. In addition, the application of biochar can promote crop root growth [92,93], regulate crop metabolic activities [94], and increase the accumulated crop biomass [95]. Zhang et al. [36] showed that the application of wheat straw biochar increased rice yield by 9–28%. In addition, a meta-analysis by Jeffery et al. [96] demonstrated that the average crop yield increased by about 10% after the application of biochar. Similar to most previous studies, we found that the application of biochar improved the soil hydrothermal conditions and increased the accumulated wheat biomass, and thus the yield increased by 3.51–16.42%.

The agricultural soil carbon budget greatly affects soil quality and crop productivity and further affects the sustainable development of agriculture [25,97], and thus carbon sequestration in farmland has become a research hotspot. Biochar is a highly stable carbon-containing material [98] and its application to soil can help to improve soil carbon inputs [29]. In addition, the application of biochar can enhance the carbon assimilation capacity of crops to fix more gaseous carbon, and the increased amount of carbon transported to the underground parts increases soil carbon sequestration [29,99,100]. Furthermore, the application of biochar can reduce the decomposition rate of soil organic carbon to slow down soil carbon losses [31,32]. In previous soil carbon sequestration studies, the NECB was widely used to assess the changes in soil carbon storage [51,101]. In particular, Wang et al. [97] showed that vegetable fields without biochar application lost carbon and had negative NECB values, whereas vegetable fields treated with biochar sequestered carbon and had positive NECB values. Similarly, Benbi et al. [102] applied biochar in a maize–wheat system and obtained a positive NECB value, and thus biochar played a positive role in soil

carbon sequestration. Similar to previous studies, we found that the application of biochar increased the soil carbon inputs and changed the NECB value from negative to positive to facilitate carbon sequestration in wheat fields.

## 5. Conclusions

In the present study, the CO<sub>2</sub>-C emission flux had negative and positive exponential relationships with the soil water content and soil temperature, respectively. However, the CH<sub>4</sub>-C uptake flux had no significant correlation with the soil water content and an inverse U-shaped quadratic function relationship with the soil temperature in wheat fields under RFRH planting. The application of biochar to wheat fields under RFRH planting reduced cumulative CO<sub>2</sub>-C emissions and increased the soil water content, soil temperature, cumulative CH<sub>4</sub>-C uptake, wheat yield, CEE, and NECB, and thus the farmland changed from a carbon source to a carbon sink. The application of biochar under RFRH planting can combine the benefits of saving water, increasing yields, reducing emissions, and facilitating carbon sequestration to ensure high-quality production from farmland in arid and semi-arid areas.
