Abstract: The use of nitrite- and nitrate-based inhibitors provides corrosion protection by the development of passive oxide film on the metal surface in reinforced concrete applications. However, the impact of the nitrite and nitrate ratio in the mixture has not been widely studied. In this study, the corrosion protection provided by $\text{NaNO}_2/\text{NaNO}_3$ inhibitor blends with ratios of 0.5:1, 1:1, and 1:0.5 were studied to maximize corrosion inhibition efficiency. The nitrite species imparted higher corrosion protection, as shown by cyclic potentiodynamic polarization, with an i_{corr} of $1.16 \times 10^{-7} \text{ A/cm}^2$ for the 1:0.5 mixture, lower than for both the 1:1 and 0.5:1 mixtures. Electrochemical impedance spectroscopy was also performed, with the 1:0.5 mixture consistently displaying high resistance values, showing an R_{ct} of $1.31 \times 10^5 \Omega \text{ cm}^2$. The effect of temperature was also assessed; the E_a 's of the corrosion reaction were calculated to be 12.1, 9.2, and 4.9 kJ/mol for the 0.5:1, 1:1, and 1:0.5 ($\text{NO}_2^-/\text{NO}_3^-$) mixtures, respectively. Density functional theory was applied to analyze the molecular properties and to determine the relationship between the quantum properties and corrosion inhibition. The ΔE of NO_2^- was found to be -5.74 eV , lower than that of NO_3^- (-5.45 eV), corroborating the experimental results. Lastly, commercially available inhibitor mixtures were investigated and nitrite/nitrate concentrations determined to evaluate their corrosion protection performance; amongst the two inhibitor blends tested, Sika was found to outperform Yara due to its greater NO_2^- concentration.

Keywords: reinforcement corrosion protection; electrochemical kinetics; potentiodynamic polarization; EIS; density functional theory; activation energy

1. Introduction

The economic impact of the corrosion of steel-reinforced concrete is significant globally, as concrete is one of the most widely used manufactured materials in construction and infrastructure [1]. Methods of corrosion protection and mitigation have been applied widely in the construction industry, including the use of stainless steel reinforcement [2,3], cathodic protection [4], protective coatings [5,6] and corrosion inhibitors [7–10]. Normally, in concrete, the alkaline environment conferred by the portlandite (Ca(OH)_2) imparts passivity by the formation of stable iron oxide films of maghemite (Fe_2O_3), goethite ($\alpha\text{-FeOOH}$), and lepidocrocite ($\gamma\text{-FeOOH}$) [11]. This passive state, however, is broken by the ingress of chloride ions [12], or by the destabilization of the passive film through carbonation of the concrete, decreasing the pH of the system [13].

Nitrites (NO_2^-) have been widely used in the inhibition of corrosion of reinforced concrete and numerous studies have examined its use in both simulated concrete pore solutions and real concrete samples [14–18]. Nitrite has been shown to be a corrosion inhibitor for steel in neutral and alkaline pH but can accelerate corrosion in acidic media [19]. Usually, nitrite is added to the concrete admixture with a mixture of components and

inhibitors [20]. The nitrite anodic inhibition mechanism for the passive layer development is governed by the electrochemical reactions shown in Equations (1) and (2) [21]:

The nitrite ions aid the formation of maghemite and lepidocrocite, which are insoluble oxides that adhere to the surface of the rebar, creating a protective passive layer [22,23]. Nitrates (NO_3^-) have been shown to be viable corrosion inhibitors in reinforced concrete [24]. The mechanism of inhibition for nitrates is directly related to the mechanism for nitrites previously discussed. Nitrates are easily reduced by the ferrous ions present in the alkaline environment to nitrites (see Equation (3)) [25]:

It is hypothesized that, because more moles of ferrous ions are oxidized to ferric, nitrate would behave as a superior corrosion inhibitor. However, in practice, this is not the case, as nitrites perform equally well or surpass nitrate corrosion inhibitors [7,26]. This has been attributed to nitrates requiring prolonged time periods for effective inhibition. Bolzoni et al. concluded that, because nitrate acts as a set accelerator, the long-term efficiency may be due to a reduction in chloride diffusion [7].

In other studies, it has been shown that nitrites show superior corrosion inhibition compared to other inorganic corrosion inhibitors; however, due to their toxicity, the liberal use of nitrites presents environmental and health concerns [27]. Therefore, there is a need to minimize the risks associated with nitrite use. Some researchers have studied the effects of nitrite with organic inhibitors such as D-sodium gluconate, which was found to enhance the adsorption of the inhibitor and to compete with chlorides for adsorption sites [28]. As nitrate is seen as an environmentally friendly alternative to nitrite for corrosion inhibition in reinforced concrete, it is hypothesized that a mixture of nitrite and nitrate might effectively improve corrosion resistance while minimizing the amount of nitrite.

In this study, corrosion inhibition using mixtures of NaNO_2 and NaNO_3 in simulated concrete pore solution (SCPS) contaminated with 0.6 M NaCl was investigated at different temperatures and the activation energy of the corrosion reaction was determined. The results were compared with commercially available corrosion inhibitors containing both NO_2^- and NO_3^- inhibitors. From the results, an optimum ratio of $\text{NO}_2^-:\text{NO}_3^-$ was determined for acceptable corrosion inhibition while minimizing the concentration of toxic NO_2^- .

2. Materials and Methods

Carbon steel rebars with composition shown in Table 1 were degreased and washed with deionized water and ethanol and air-dried. A copper wire was attached to the rebar and the test area was delimited by non-conductive red stopping lacquer. All chemicals used were of reagent grade with no further purification. Commercially available $\text{NO}_2^-/\text{NO}_3^-$ corrosion inhibitor blends were obtained from Sika and Yara. The chemical composition of NO_2^- and NO_3^- ions were obtained using UV-vis spectroscopy by the Griess reagent method [29,30]. First, a calibration curve was obtained with standard NO_2^- and an R-squared value of 0.998 was obtained. Then, the NO_2^- concentration was determined by reacting the inhibitor solution with Griess reagent (0.2 wt% N-(1-naphthyl)ethylenediamine dihydrochloride and 2 wt% sulfanilic in 5 wt% phosphoric acid) for 30 min, the resulting compound was observed by UV-vis at 548 nm. The Griess reaction makes nitrite concentration measurable by UV-vis spectroscopy by reacting nitrite to produce a larger azo dye. The reaction is achieved by reacting NO_2^- in acidic conditions with sulfanilic acid ($\text{C}_6\text{H}_7\text{NO}_3\text{S}$). This forms the diazonium cation $\text{H}_5\text{OSC}_6\text{N}\equiv\text{N}(+)$. This reacts with the aromatic 1-naphthylamine ($\text{C}_{10}\text{H}_9\text{N}$) to form the water-soluble azo dye ($\text{HO}_3\text{SC}_6\text{H}_4\text{-NN-}\text{C}_{10}\text{H}_6\text{NH}_2$) which has a red-violet color. The NO_3^- content was determined by mixing

the commercial inhibitors with Cd powder for 12 h at 30 °C, thus through redox reaction the NO_3^- ions are reduced to NO_2^- ions after filtering the Cd, the concentration was measured by the Griess method. The known NO_2^- concentration in the original inhibitor solution was then subtracted from the measurements obtained after Cd reduction, providing the concentration of NO_3^- ions in the commercial corrosion inhibitors.

Table 1. Elemental composition of carbon steel rebar specimens (wt%).

Electrochemical tests were conducted in a three-electrode configuration using a Gamry Series 600 potentiostat, a saturated calomel reference electrode, a graphite rod counter electrode, and the steel rebar as the working electrode. The test solution used was 250 mL saturated calcium hydroxide as the SCPS contaminated with 0.6 M NaCl. The corrosion inhibitors were added in molar ratios of 0.5:1, 1:1, and 1:0.5 (NaNO_2 : NaNO_3) while maintaining a 1:1 molar ratio of total inhibitor to chloride ions; these were added directly to the solution and allowed to mix for at least 30 min prior to testing. First, the open circuit potential (OCP) was monitored until a steady state value was reached after about 1 h. Then electrochemical impedance spectroscopy (EIS) was recorded at OCP between frequency ranges of 10^5 Hz and 10^{-2} Hz with an applied 10 mV AC signal using 10 points per decade. Lastly, cyclic potentiodynamic polarization (CPP) was performed between $-0.2 V_{\text{OCP}}$ and $+0.2 V_{\text{OCP}}$ using a 0.1667 mV/s scan rate according to ASTM G61-86 [31]. Finally, adsorption isotherms were obtained using a constant temperature water bath maintained at 25, 35, and 45 °C. All tests were performed in triplicate.

After electrochemical testing, the rebar samples were rinsed with DI and dried with compressed air. Then, imaging and energy-dispersive X-ray spectroscopy (EDX) were performed on the rebar samples after electrochemical testing and exposure to the test solution for 3 h using a Tescan Lyra 3 scanning electron microscope (SEM) with an excitation voltage of 15 kV and a working distance of 8 μm .

Density functional theory (DFT) calculations were performed using Gaussian 16 revision A.03 software. The input files for the corrosion inhibitors were prepared with GausView 6.06.16. The molecules were fully optimized using DFT employing a B3LYP functional [32], and using a 6-31G (d,p) basis set to determine HOMO, LUMO, Mulliken charges, electron density mapping, and quantum properties for this study [33].

3. Results

The electrochemical resistance and capacitance values of the rebar-inhibitor interface were measured by EIS and the resulting Nyquist plots are shown in Figure 1. The results obtained in 25 °C in (Figure 1a) showed similar impedance values, of the order of $10^5 \Omega \text{ cm}^2$, between the corrosion inhibitor molar ratios of NO_2^- : NO_3^- while maintaining a total inhibitor:chloride ratio of 1:1. The 1:1 and 1:0.5 NO_2^- : NO_3^- ratios showed improved impedance with higher concentrations of NO_2^- ; similarly, the 35 and 45 °C conditions displayed a greater difference in impedance, with the inhibitor mixture with the highest NO_2^- concentration giving the best inhibitive performance.

The EIS results were fitted to an electrical equivalent circuit (EEC), as shown in Figure 2, with two relaxation processes, high frequencies revealing the development of a passive oxide film and lower frequencies modeling the electrochemical double layer. The EEC consisted of a solution resistance (R_s), and two R - CPE time constants indicating a passive film resistance (R_f) and film capacitance represented by a constant phase element (CPE_f), in addition to charge transfer resistance (R_{ct}) and electrochemical double-layer capacitance (CPE_{dl}). The R_s values did not vary greatly with temperature, remaining around $20 \Omega \text{ cm}^2$ for all tests (see Table 2). The R_f values showed the greatest passive film resistance for the 1:0.5 and 1:1 NO_2^- : NO_3^- inhibitor ratio tests, showing a higher passive film resistance with higher concentrations of NO_2^- . Furthermore, the R_{ct} values indicated that the 1:0.5 inhibitor ratio

for $\text{NaNO}_2:\text{NaNO}_3$ provided the best corrosion inhibition, as it maintained the highest values. Moreover, the 1:1 ratio also provided higher R_{ct} values that were similar to those found for 1:0.5, which were an order of magnitude higher than for the 0.5:1 inhibitor mixture.

Figure 1. Nyquist plots of NaNO_2 and NaNO_3 obtained in simulated concrete pore solution contaminated with 0.6 M NaCl under constant temperature of (a) 25 °C, (b) 35 °C, and (c) 45 °C.

Figure 2. The electrochemical equivalent circuit model of the EIS data for carbon steel rebar in SCPS contaminated with 0.6 M Cl^- in the presence of both NaNO_2 and NaNO_3 corrosion inhibitors.

A CPE was used to model the non-ideality of the capacitance. The effective capacitance of the film ($C_{\text{eff},f}$) and the electrochemical double layer ($C_{\text{eff},dl}$) were calculated using the relationship provided by Brug et al. [34], and Mansfeld et al. [35], respectively (see Equations (4) and (5)):

$$C_{\text{eff},dl} = Y_{dl}^{1/n_{dl}} \left(\frac{1}{R_e} + \frac{1}{R_{ct}} \right)^{(n_{dl}-1)/n_{dl}} \quad (4)$$

$$C_{\text{eff},f} = Y_f (\omega_m'')^{n_f-1} \quad (5)$$

where Y_{dl} and Y_f are the admittance of the electrochemical double layer and passive film, respectively; n_{dl} and n_f are the exponents for the CPE of the double layer and passive film, respectively; and ω_m'' is the impedance at which the imaginary component of the impedance is maximized. The $C_{\text{eff},f}$ values calculated for each inhibitor mixture maintained the same order of magnitude for all the tests; however, the 1:0.5 $\text{NO}_2^-:\text{NO}_3^-$ inhibitor mixture showed the lowest capacitance values, indicating an improved passive oxide film. More significantly, by analyzing the calculated $C_{\text{eff},dl}$, a clear distinction was able to be made as the 1:0.5 inhibitor ratio sample consistently displayed the lowest capacitance values of an order of magnitude less than the 0.5:1 sample, with the 1:1 sample showing middling values. The lower $C_{\text{eff},dl}$ values indicated improved passivity imparted by the

NaNO₂ through its ability to form a stable passive layer. The thickness of the passive film formed can be indirectly measured by EIS using the relationship in Equation (6):

$$d_{\text{eff}} = \frac{\varepsilon \varepsilon_0}{C_{\text{eff},f}} \quad (6)$$

where d_{eff} is the passive film thickness, ε is the dielectric constant of iron oxide ($\varepsilon = 30$) [36], and ε_0 is the permittivity of the vacuum 8.85×10^{-14} F cm⁻¹. The 1:0.5 samples showed the highest d_{eff} values for each temperature condition, while the 1:1 samples displayed passive film thickness values between that of the 1:0.5 and 0.5:1 NO₂⁻:NO₃⁻ corrosion inhibitor samples, corroborating the trend of greater nitrite concentrations imparting improved corrosion resistance by formation of a thicker passive film.

Table 2. EIS parameters obtained from steel rebars immersed in SCPS with 0.6 M NaCl with and without corrosion inhibitors in molar ratios of 0.5:1, 1:1, and 1:0.5 for NaNO₂:NaNO₃ at 25, 35, and 45 °C.

The CPP plots obtained for each ratio of inhibitors at 25, 35, and 45 °C are shown in Figure 3. The curves obtained for 25 °C in Figure 3a showed an increased E_{corr} value with higher concentrations of NaNO₂ inhibitor, demonstrating the most stable passive film formed on the rebar compared to the inhibitor mixtures with less NaNO₂ and higher concentrations of NaNO₃. Specifically, the 1:0.5 inhibitor ratio tests showed the most noble E_{corr} value of −303 mV_{SCE}, see Table 3, and a low i_{corr} below 1 μA/cm², the accepted limit for active corrosion to occur in simulated concrete pore solution. This passive E_{corr} value, along with the highest calculated anodic Tafel slope (β_a), indicated the lowest reaction kinetics of the anodic dissolution which govern the corrosion mechanism for rebar at alkaline pH with chlorides [37]. Furthermore, the hysteresis of the reverse scan for the 1:0.5 exposed sample showed high reversibility due to the stable passive film formed, showing very little change on the rebar surface compared to the 1:1 and 0.5:1 NO₂⁻:NO₃⁻ corrosion inhibitor samples. The CPP curves at 35 °C shown in Figure 3b displayed a similar trend. The 1:0.5 sample showed the most passive E_{corr} of −299 mV_{SCE}, for all the temperature ranges tested. The i_{corr} values also indicated passivity for all the inhibitor ratios with values below 1 μA/cm², with the 1:0.5 ratio showing the lowest i_{corr} value of 2.07×10^{-7} A/cm². The 1:0.5 sample showed the most reversible electrochemical reaction, with least changes in the passive film and surface of the rebar. Finally, for the 45 °C electrochemical results, the 1:0.5 exposed sample showed the most passive E_{corr} value of all the tests with a value of −257 mV_{SCE} and the lowest i_{corr} value of 7.75×10^{-7} A/cm². The reversibility of the CPP curves was the poorest under the 45 °C condition; however, the 1:0.5 sample reverse scan showed the least active surface, as the reverse scan had the most passive potentials and lower current density values. Overall, an improved inhibitive performance for E_{corr} and i_{corr} values with increased amount of NaNO₂ corrosion inhibitor was found. Moreover, the effect of NO₂⁻ on the inhibited anodic reaction kinetics was evidenced by the Tafel slopes shown in Table 3; increased amounts of NaNO₂ correlated with higher β_a , thus, a lower electrochemical dissolution reaction.

Figure 3. CPP plots of NaNO_2 and NaNO_3 obtained in SCPS contaminated with 0.6 M NaCl under constant temperature of (a) 25 °C, (b) 35 °C, and (c) 45 °C.

Table 3. Corrosion kinetic parameters obtained from steel rebars immersed in SCPS with 0.6 M NaCl with and without corrosion inhibitors in molar ratios of 0.5:1, 1:1, and 1:0.5 for NaNO_2 : NaNO_3 at 25, 35, and 45 °C.

Temperature °C	Molar Ratio $\text{NO}_2^-:\text{NO}_3^-$	E_{corr} mV _{SCE}	i_{corr} A/cm ²	β_a V/dec	$-\beta_c$ V/dec	IE %	R_p $\Omega \text{ cm}^2$

	0.5:1	−345	4.32×10^{-7}	0.229	0.185	71	1.33×10^5
	1:1	−341	1.51×10^{-7}	0.257	0.159	90	1.11×10^5
	1:0.5	−303	1.16×10^{-7}	0.503	0.187	93	2.41×10^5
35	Control	−440	2.01×10^{-6}	0.110	0.191	−	−
	0.5:1	−325	6.38×10^{-7}	0.115	0.096	68	1.78×10^5
	1:1	−326	4.34×10^{-7}	0.211	0.142	78	1.82×10^4
	1:0.5	−299	2.07×10^{-7}	0.412	0.354	90	1.05×10^5
45	Control	−449	3.81×10^{-6}	0.098	0.208	−	−
	0.5:1	−343	1.27×10^{-6}	0.183	0.229	67	2.50×10^4
	1:1	−305	9.07×10^{-7}	0.191	0.191	76	1.16×10^4
	1:0.5	−257	7.75×10^{-7}	0.204	0.201	80	1.72×10^4

Additionally, the corrosion inhibitor efficiency was calculated using Equation (7):

$$\text{IE (\%)} = \frac{i_{\text{corr}(0)} - i_{\text{corr}(i)}}{i_{\text{corr}(0)}} \times 100\% \quad (7)$$

where $i_{\text{corr}(0)}$ and $i_{\text{corr}(i)}$ are the corrosion current density for the control and inhibitor dosed samples, respectively.

The anodic scan of the CPP curves highlights the kinetics of the anodic reaction, as well as the state of the passive layer, since the carbon steel rebars are in alkaline solution that facilitate stable passive oxide film formation [38]. The area bounded by the forward and reverse scan indicates how active the surface is becoming, with a greater area indicating increased current densities relative to the i_{corr} . This can be visualized in Figure 4a, where the areas are shown overlapping for the tests at 25 °C previously discussed. Here, it can clearly be seen that the control sample with no inhibitor had an area magnitude larger than for the inhibitor samples and that the 1:1 and 0.5:1 $\text{NO}_2^-:\text{NO}_3^-$ samples displayed similar anodic areas. The 1:0.5 samples showed negative hysteresis, implying that the samples became

more passive after the polarization scan. This was caused by the polarization facilitating the formation of the passive film from the corrosion inhibitors. This trend was followed for the remaining temperatures tested; the 1:0.5 sample showed the lowest amount of positive hysteresis and the 0.5:1 samples showed the worst behavior of the mixtures tested.

Figure 4. The representation of (a) the anodic areas of the CPP curves at 25 °C in SCPS with 0.6 M NaCl, and (b) the IE obtained from SCPS with 0.6M NaCl at 25, 35, and 45 °C.

The IE graph is plotted against temperature for each inhibitor ratio in Figure 4b. Again, the greater concentrations of nitrite in the 1:0.5 and 1:1 $\text{NO}_2^-:\text{NO}_3^-$ mixtures showed the best performance with the highest IE values for all temperatures, while the 0.5:1 mixture had the lowest. The contrast between the three mixtures increased with temperature, with the 0.5:1 inhibitor mixture having only 40% IE at 40 °C, almost half the IE measured at 25 °C. This was because the temperature increased the corrosion reaction rates and hindered the adsorption reaction of the inhibitors to provide a stable and protective passive oxide film [37]. The 1:0.5 and 1:1 $\text{NO}_2^-:\text{NO}_3^-$ mixtures, however, showed a slight increase in IE as the temperature increased, likely as a result of an increase in the rate of the nitrite inhibition mechanism, thus forming a stable passive oxide layer.

The activation energy for the corrosion reaction for each corrosion inhibitor solution was calculated using the Arrhenius equation shown in Equation (8):

$$\ln i_{\text{corr}} = \ln A - \frac{E_a}{RT} \quad (8)$$

where R is the universal gas constant, T is the absolute temperature, and A is the pre-exponential factor. The i_{corr} values were obtained from the Tafel analysis of the polarization curves for the varying inhibitor ratios at different temperatures.

According to the Arrhenius plot in Figure 5, the slope of the regression line has a slope equal to $-E_a/RT$, thus E_a can be calculated. The E_a values were calculated to be 12.1 kJ/mol, 9.2 kJ/mol, and 4.9 kJ/mol for the 1:0.5, 1:1, and 0.5:1 ratios of $\text{NO}_2^-:\text{NO}_3^-$, respectively. The trend for E_a followed the results from both EIS and CPP, which confirmed that higher concentrations of NO_2^- improved corrosion resistance, as a higher E_a indicates a higher energy barrier for the corrosion reaction to occur. The 1:0.5 sample displayed the highest E_a , with the most efficient corrosion inhibition of the tested $\text{NO}_2^-:\text{NO}_3^-$ mixtures.

Figure 5. Arrhenius plots for the corrosion inhibitor mixtures of 0.5:1, 1:1, and 1:0.5 NaNO₂:NaNO₃ in 0.6 M NaCl.

The corrosion products on the steel rebar were examined by SEM; images for the 0.5:1, 1:1, and 1:0.5 NaNO₂:NaNO₃ inhibitor mixture samples are shown in Figure 6a–c, respectively. The areas examined were near the corrugated section of the rebar, where the presence of corrosion products was seen, as these areas experienced the highest residual stress after cold working, and were thus the most active areas [39,40]. The amount of corrosion products observed was found to decrease with increasing concentrations of NO₂[−], in agreement with the electrochemical results. EDX spectra were obtained to analyze the atomic composition and are shown below the SEM images. The 1:1 and 1:0.5 NO₂[−]:NO₃[−] ratios showed measurements of approximately 63% Fe and 36% O; this ratio is consistent with the occurrence of protective γ-FeOOH oxides facilitated by the NO₂[−] inhibitor mechanism [15]. The 0.5:1 inhibitor ratio produced detectable amounts of Cl[−], while the other mixtures did not show detectable amounts of Cl[−], evidencing increased corrosion through the process of chloride attack. Photographs of the rebars after testing at 45 °C are shown in Figure 7. The most notable corrosion products were found for the control, which contained no corrosion inhibitors. The 0.5:1 rebar showed some corrosion products near the corrugated section, where small pits were observed, and some discoloration of the test solution was observed due to the formation of soluble oxides. The 1:1 and 1:0.5 NO₂[−]:NO₃[−] exposed rebar samples did not show noticeable corrosion products on the surface due to their significantly improved corrosion inhibition and the formation of protective oxide films.

The commercially available corrosion inhibitors, Sika and Yara, were tested in SCPS containing 0.6 M NaCl with carbon steel rebar at 25 °C [41]. The concentrations of commercial inhibitor were determined from a 1:1 ratio of total inhibitor (NO₂[−] and NO₃[−]) to chloride ions in solution. The Nyquist plot in Figure 8 shows the EIS results of the two commercial inhibitors and a control sample with no inhibitor present. The Sika inhibitor showed larger corrosion resistance values than the Yara inhibitor, as the Sika inhibitor contained a two-fold higher weight fraction of NO₂[−] inhibitor than Yara. Additionally, the parameters obtained from the EIS test and fitting of the values to the EEC in Figure 2 are shown in Table 4.

Figure 6. SEM and EDX images for steel rebar exposed to (a,d) 0.5:1, (b,e) 1:1, and (c,f) 1:0.5 molar ratios of $\text{NO}_2^-:\text{NO}_3^-$ in SCPS contaminated with 0.6 M NaCl.

Figure 7. Photographs of the rebars after exposure to SCPS with 0.6 M NaCl and inhibitor blends of 0.5:1, 1:1, and 1:0.5 $\text{NaNO}_2:\text{NaNO}_3$ at 45 °C.

Figure 8. Nyquist plots for steel rebar exposed to commercial corrosion inhibitors blends (Sika and Yara) in 0.6 M NaCl SCPS.

Table 4. The EIS parameters obtained for rebar exposed to commercial corrosion inhibitor blends (Sika and Yara) in simulated concrete pore solution with 0.6 M NaCl.

Corrosion Inhibitor Blend	R_s $\Omega \text{ cm}^2$	R_f $\Omega \text{ cm}^2$	R_{ct} $\Omega \text{ cm}^2$	Y_f $\text{S cm}^{-2} \text{ s}^{n_f}$	n_f	Y_{dl} $\text{S cm}^{-2} \text{ s}^{n_{dl}}$	n_{dl}	χ^2
Yara	16	969	2.44×10^5	3.02×10^{-5}	0.71	6.12×10^{-6}	0.75	2.99×10^{-3}
Sika	16	1230	1.25×10^7	2.82×10^{-5}	0.70	2.14×10^{-6}	0.78	4.68×10^{-3}
Control	21	20	4.72×10^3	5.46×10^{-4}	0.84	9.15×10^{-6}	0.71	2.74×10^{-3}

The R_f values obtained showed the higher development of the Sika compared to the Yara commercial corrosion inhibitor blend; however, both inhibitors showed R_f values nearly one order of magnitude higher than those for the control sample. The R_{ct} values showed a greater difference between the inhibitors with Sika measuring $1.25 \times 10^7 \Omega \text{ cm}^2$, while the Yara inhibitor measured $2.44 \times 10^5 \Omega \text{ cm}^2$. The Sika inhibitor also displayed the lowest capacitance for the film and the electrochemical double layer, indicating improved passive film formation and the greatest corrosion resistance of the two mixtures.

The CPP curves of the commercial corrosion inhibitor blends tested are shown in Figure 9. The Sika and Yara samples showed similar trends with increased E_{corr} values (see Table 5), negative hysteresis and decreased current values. The Sika sample showed the most noble E_{corr} with a value of $-292 \text{ mV}_{\text{SCE}}$ and the Yara with a value of $-337 \text{ mV}_{\text{SCE}}$; both values were more noble than the control, indicating less susceptibility of the surface to corrosion. Furthermore, the i_{corr} values calculated by Tafel analysis showed the same trend, with the Sika sample having an i_{corr} value of $9.38 \times 10^{-7} \text{ A/cm}^2$, above that of the Yara sample of $5.83 \times 10^{-7} \text{ A/cm}^2$.

Figure 9. CPP curves obtained for steel rebars exposed to commercial corrosion inhibitor blends (Sika and Yara) in SCPS with 0.6 NaCl.

Table 5. CPP parameters obtained for steel rebars exposed to commercial corrosion inhibitor blends (Sika and Yara) in SCPS with 0.6 NaCl.

Corrosion Inhibitor Blend	E_{corr} mV _{SCE}	i_{corr} A/cm ²	IE %
Sika	−292	4.27×10^{-7}	71
Yara	−336	5.62×10^{-7}	62
Control	−487	1.49×10^{-6}	-

Finally, both commercial corrosion inhibitors blends displayed negative hysteresis during the reverse scan, indicating less active surfaces after polarization and stable passive film formation. Both commercial $\text{NO}_2^-/\text{NO}_3^-$ blends imparted corrosion inhibition to steel rebars in SCPS; however, the Sika blend enabled an improved stable passive film with decreased dissolution kinetics.

The optimized structures and molecular electrostatic potential mapping, shown in Figure 10, enabled elucidation of the Mulliken atomic charges (MAC) (see Figure 10a,b). It was observed that the electron density did not vary greatly over the molecules, leading to flat adsorption on the metal surface with contact of each atom. However, for the NO_3^- , the charge difference was greater, with a positive MAC located on the central N atom due to the resonance of the π -bonding between the N and the O atoms which have a higher electron affinity [42].

Figure 10. The optimized molecular structure with Mulliken charges for (a) NO_2^- , and (b) NO_3^- ; and the electron density mapping for (c) NO_2^- , and (d) NO_3^- .

The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) surfaces are shown in Figure 11. The HOMO surfaces provide information on the sites of the molecule in which the most loosely bound electrons are likely to be donated to the metal, while the LUMO surfaces show the regions in which electrons from the metal are likely to be back-donated to the inhibitor [41,43]. For NO_2^- , the largest portion of the HOMO concentrated around the π -bonds of the oxygen bonding where resonance occurs. The LUMO of the NO_2^- was concentrated near the nitrogen end of the molecule. The HOMO of the NO_3^- showed outer oxygen molecules, while the LUMO was symmetrical and evenly spread across the molecule.

Figure 11. The distribution of electron density for (a) NO_2^- HOMO, (b) NO_2^- LUMO, (c) NO_3^- HOMO, and (d) NO_3^- LUMO using DFT/B3LYP/6-31G (d, p).

The computed quantum properties of the HOMO and LUMO electronic state energies E_{HOMO} and E_{LUMO} , respectively, and the energy gap (ΔE), and dipole moment (μ_D) are listed in Table 6. Higher values of E_{HOMO} were associated with enhanced ability of the inhibitor to donate electrons to the vacant metal atom orbitals, and lower values of E_{LUMO} indicated an increased tendency of the inhibitor to accept back-donated electrons from

the metal atoms [44]. The ΔE value can be used to assess the relative reactivity of the inhibitor molecule to the metal atom; lower ΔE values may indicate better inhibition efficiency [45,46]. From these DFT calculations and the trends described, it was determined that NO_2^- behaved as a superior corrosion inhibitor relative to NO_3^- due to its higher E_{HOMO} and lower ΔE . Additionally, the μ_{D} values of the inhibitors were close in value; however, the higher μ_{D} of the NO_2^- may also have contributed to its increased corrosion inhibition [47].

Table 6. Quantum chemical parameters for NO_2^- and NO_3^- in aqueous phase calculated using DFT/B3LYP/6-31G (d, p).

Inhibitor	E_{HOMO} eV	E_{LUMO} eV	ΔE eV	μ_{D} eV
NO_2^-	−5.55	−0.55	−5.74	121.91
NO_3^-	−6.49	−0.78	−5.45	199.55

4. Conclusions

The corrosion protection of inhibitor mixtures of NaNO_2 and NaNO_3 were studied in SCPS contaminated with 0.6 M NaCl using CPP and EIS electrochemical techniques. The results were correlated with quantum calculation results from DFT analysis. The following conclusions can be drawn:

- A mixture of NaNO_2 and NaNO_3 corrosion inhibitors can successfully protect carbon steel rebar in simulated concrete pore solution with 0.6 M NaCl. All mixtures tested, including 1:0.5, 1:1, and 0.5:1 $\text{NO}_2^-:\text{NO}_3^-$ ratios, showed improvement in the corrosion properties compared to the control test with no inhibitors. The best performing inhibitor mixture was the 1:0.5 ratio, showing an i_{corr} of 1.16×10^{-7} A/cm² at 25 °C.
- Greater concentrations of NO_2^- were associated with higher corrosion inhibition; specifically, the 1:0.5 and 1:1 $\text{NO}_2^-:\text{NO}_3^-$ solutions showed the lowest i_{corr} and highest resistance values associated with passive film (R_{f}) values of 1.67×10^3 and 1.60×10^3 Ω cm², respectively, and corrosion process (R_{ct}) values of 1.31×10^5 and 2.39×10^5 Ω cm², respectively. The activation energy (E_{a}) also followed this trend, the 1:0.5 inhibitor mixture showing the highest activation energy of 12.1 kJ/mol, indicating that a greater energy barrier needed to be overcome for the corrosion process to be initiated with higher amounts of nitrite compared to nitrate inhibitors. Therefore, the dominating inhibitor in the mixture was found to be NO_2^- . The inhibitor blends of 1:0.5 and 1:1 $\text{NaNO}_2:\text{NaNO}_3$ showed the best corrosion inhibition; thus, the optimal ratio is 1:1 to maximize inhibition efficiency while minimizing NO_2^- , as it is toxic and can be harmful to the environment.
- Finally, by comparison of two commercially available mixtures, the inhibitor mixture with the higher nitrite concentration (Sika) showed the most passive E_{corr} of −292 mV_{SCE} and a lower i_{corr} of 4.27×10^{-7} A/cm², corroborating the hypothesis that nitrite dominated the inhibition process of the $\text{NO}_2^-:\text{NO}_3^-$ mixture.
- By DFT analysis of the inhibitors, the E_{HOMO} , E_{LUMO} , ΔE , and dipole moment values obtained were found to be consistent with the experimental results. The E_{HOMO} values indicated that nitrite more readily donated its electrons to the metal atoms and that the ΔE was lower, −5.74 eV, for the higher nitrite mixture (1:0.5), which has been correlated with better corrosion inhibition in the literature.
