Received: 19 December 2018; Accepted: 9 January 2019; Published: 15 January 2019

Abstract: Removal of hexavalent chromium had attracted much attention as it is a hazardous contaminant. An electrocoagulation-like technology electro-reduction was applied. The chromium (VI) in the wastewater was reduced to chromium (III) by the electron supplied by electricity power and Fe^{2+} , formed from corrosion of steel electrodes in acidic conditions. The mechanism and parameters affecting the reaction were investigated. The results optimized by response surface methodology indicated that the influence of single factor on the reduction efficiency followed the order: A: dosage of H_2SO_4 > C: reaction time > D: reaction temperature > B: current intensity. The reduction efficiency was hardly affected by current intensity, while it was increased with the increasing of reaction time and acid concentration. The reducing agent, Fe^{2+} and extra free electron, acted as a reducing agent and could easily reduce hexavalent chromium to trivalent chromium at high temperatures in an acidic medium.

Keywords: electro-reduction; chromium; acidic medium

1. Introduction

Chromium is an important strategic metal widely used in many fields due to its excellent properties [1–5]. In the earth, chromium mainly exists in the oxidative states of hexavalent chromium and trivalent chromium. The chromium (III) compounds are relatively stable and have low solubility and mobility. Chromium (VI) mainly exists as chromate (CrO_4^{2-} , HCrO_4^-) and dichromate ($\text{Cr}_2\text{O}_7^{2-}$), which has high solubility. The removal of chromium (VI) has attracted much more attention, as it is a hazardous contaminant [6,7].

Currently, many remediation techniques have been developed to remove heavy metal ions from waste water. It can be divided into three species. The traditional one is physical methods, like adsorption [8–11], ion exchange [12], and membrane filtration [7], which are mainly conducted by their physical properties. Due to the different chemical properties of chromium (VI) and chromium (III), chemical precipitation [13], coagulation [14], and chemical reduction [15,16] are often used to remove chromium (VI). Additionally, some biological treatments [17,18] (phytoremediation [19]) are also applied to remove chromium (VI) in waste water and groundwater. Lead sulfate as a precipitation is used to precipitate chromium (VI) and it can remove chromium (VI) from 0.2 mol/L to 0.15 mmol/L, as shown in a recent study [13], but lead sulfate is a second pollutant, which is harmful for the environment. At the same time, difficulties and challenges like high costs, large scale application, and causing secondary pollution still remain in current technologies. It is needed to overcome these challenges and develop new, effective techniques for removal of chromium (VI).

Electricity acting as a clean source is widely used in hydrometallurgy, like electro-oxidation technology [20–22], and treatment of different wastewater, like electrocoagulation [23–25]. Electrocoagulation involves the generation of coagulants by dissolving metal electrodes or free electrons. The metal ions formed are metal hydroxides, like Al(OH)^{2+} , Al(OH)_2^+ , and Al(OH)_4^- for Al electrode, and Fe(OH)^{2+} and Fe(OH)_3 for Fe electrode. These metal hydroxides have large surface areas and can adsorb soluble organic compounds. In this paper, an electrocoagulation-like technology electro-reduction is applied to reduce Cr (VI) to Cr (III). The mechanisms and parameters affecting the reaction are investigated, including dosage of H_2SO_4 , reaction time, reaction temperature, and current intensity. Response surface methodology [26–28] is also used to predict the optimal reaction conditions and observe the interactions between parameters.

2. Materials and Methods

2.1. Materials

All chemicals were of analytical grade, including potassium dichromate ($\text{K}_2\text{Cr}_2\text{O}_7$) and sulfuric acid (H_2SO_4), which were collected from Kelong Co., Ltd, Chengdu, China, and used as received without purification.

2.2. Experimental Procedure

Reduction experiments were carried out in a batch mode to evaluate the reduction efficiency of electricity for chromium (VI) ions from aqueous solutions. In the batch experiments, a stock solution of 1.000 g/L chromium (VI) was prepared by dissolving a certain $\text{K}_2\text{Cr}_2\text{O}_7$ in distilled water. The acidic medium was prepared by adding different volumes of H_2SO_4 , the current was from a set of electric supply, the anode and cathode used in the experiments were steel slice (2×2 cm), and the distance of the two electrodes was 2 cm. Further, in each set of experiments, 100 mL of chromium (VI) was added into a beaker and agitated in a thermostat water-bath shaker at 500 rpm. During the experiments, the samples were collected at different intervals (5 min), and analyzed for residual concentration of chromium (VI) in the solution [13].

The concentration of chromium (VI) was determined by inductive couple plasma-optical emission spectrometry (ICP-OES). The reduction efficiency (η) was calculated as Equation (1):

$$\eta = \frac{C_1 \cdot V_1 - C_2 \cdot V_2}{C_1 \cdot V_1} \quad (1)$$

where C_1 and C_2 are the concentration of chromium in the solution before and after the experiment, g/L. V_1 and V_2 is the volume before and after the experiment, L.

2.3. Experimental Design and Optimization Method

The adoption of response surface methodology (RSM) to optimize a known process is easy, practical, and economical. Successful RSM optimizations usually consist of three steps. The first step was to design appropriate experiments to efficiently assess the model parameters. The second step was to develop a polynomial model that can be applied to the experimental data through regression, and to verify the model's suitability by applying a statistical test (e.g., *lack-of-fit* or *F-test*) [29–31]. The final step was to determine the values of factors that result in the best conditions. A first or second-order polynomial was usually used for RSM analysis, and a second order polynomial was preferred for responses that included a curvature. The general form of such a polynomial is as follows:

$$y = a_0 + \sum_{i=1}^k a_i x_i + \sum_{i=1}^k a_{ii} x_i^2 + \sum_{i=1}^k \sum_{j=1}^k a_{ij} x_i x_j^2 + \epsilon \quad (i < j) \quad (2)$$

where y is the predicted response, a_0 is a constant, a_i is the i th linear coefficient, a_{ii} is the i th quadratic coefficient, a_{ij} is the i th interaction coefficient, x_i is an independent variable, k is the number of factors, and ε is the associated error.

The coefficients of the model were predicted using regression. Details of the parameter estimations for such a model have been reported previously [29–31]. Central composite design (CCD), which was utilized in this study, was the most popular second-order experimental design, and was an efficient approach to providing sufficient information to test the fitness of a model. The CCD approach did not require numerous design points; therefore, it saved the expense and time associated with completing experiments. Many experiments in which CCD had been applied had included three sets: (1) factorial factorial runs (2^{k-1}), which studied factors at -1 (minimum) and $+1$ (maximum) levels; (2) center-point runs, which examined factors at a center point of a design space and aided in the understanding of curvature and data replication to evaluate pure errors; and (3) axial or star-point runs ($2k$), which set all factors to 0 (i.e., the center point), except for one factor with values of $+\alpha$ and $-\alpha$ [29–31].

In this study, the Design-Expert software (Version 8.0.6) was used to design the experiments. CCD was applied to investigate the impact of process parameters on the leaching efficiency of vanadium from vanadium-chromium residue. The experiment results were incorporated to determine an empirical equation that could predict the optimal operating conditions. The operation factors included the mass ratio of NaOH to vanadium-chromium residue, volume ratio of H_2O_2 to mass of vanadium-chromium residue, reaction time, reaction temperature, stirring rate, and liquid-to-solid ratio. The satisfaction degree of the polynomial equation developed through a regression of Equation (2) was assessed on the basis of R^2 and R_{Adj}^2 . R^2 was a measurement of the amount of variation around the mean; it was determined for a model using Equation (3). R_{Adj}^2 was a measurement of the amount of variation around the mean; it was determined by experiments and was regulated for the number of terms in the model using Equation (4).

$$R^2 = 1 - \frac{S_{\text{residual}}}{S_{\text{model}} - S_{\text{residual}}} \quad (3)$$

$$R_{Adj}^2 = 1 - \frac{S_{\text{residual}} / Z_{\text{residual}}}{(S_{\text{model}} + S_{\text{residual}}) / (Z_{\text{model}} + Z_{\text{residual}})} \quad (4)$$

where S is the sum of squares and Z is the degrees of freedom. The statistical importance of the model was verified with adequate precision using Equations (5) and (6). These equations were used to determine the signal-to-noise ratio.

$$\text{Adequate precision} = \frac{\max \hat{y} - \min \hat{y}}{\sqrt{\bar{V}(\hat{y})}} \quad (5)$$

$$\bar{V}(\hat{y}) = \frac{1}{n} \sum_{i=1}^n V(\hat{y}_i) = \frac{p\sigma^2}{n} \quad (6)$$

where \hat{y} is the predicted response, p is the number of model parameters, σ^2 is the residual mean square, and n is the number of experiments.

3. Results and Discussion

3.1. Reduction of Chromium (VI)

3.1.1. Reaction mechanism

The electro-reduction process, similar to electrocoagulation, which is expressed in Figure 1, involved the following stages of reducing agent formation and subsequent reduction of chromium (VI) and chromium (III).

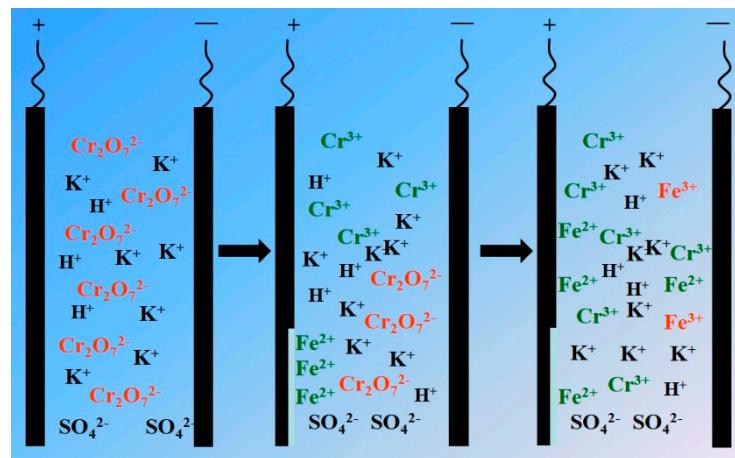

Figure 1. The reaction model for the electro-reduction process.

The first step was the formation of reducing agent. During the reduction process, a potential was applied. The anode steel slice was almost made up of iron and it was oxidized by electricity and formed Fe^{2+} . The mechanism was described in Equation (7), as follows:

Anode:

Cathode:

Overall:

The second step was the reduction reaction between reducing agent and oxidant. In this process, it was the reaction between Fe^{2+} and chromium (VI). The reactions were described in Equations (11) to (15) by taking the pH of wastewater into account.

$0.5 < \text{pH} < 6.5$:

$6.5 < \text{pH} < 7.5$:

$\text{pH} > 7.5$:

The extra electrons emitted were also reducing agents and could also reduce chromium (VI) to chromium (III).

3.1.2. Effect of Dosage of H_2SO_4

The effect of dosage of H_2SO_4 on the reduction efficiency was investigated, while other conditions remained constant—initial concentration of Cr (VI) of 1.000 g/L, current density of 0.05 A, and reaction

temperature of 30 °C. The dosage of H₂SO₄ was quantified as the volume, set as 0.00 mL, 0.25 mL, 0.50 mL, 0.75 mL, and 1.00 mL. The results were shown in Figure 2.

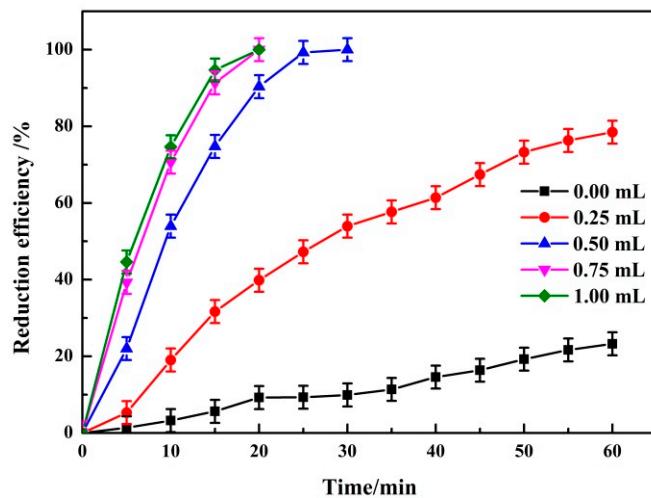

Figure 2. Effect of volume of H₂SO₄ on reduction efficiency of chromium. (Initial concentration of Cr (VI) = 1.000 g/L, current intensity = 0.05 A).

The results indicated that the reduction efficiency of chromium increased with the increasing of reaction time and acid concentration. The reduction of chromium (VI) in the process was acid-dependent, and higher chromium (VI) reduction efficiency could be achieved at high acid concentration. The acceleration of Cr (VI) reduction in the system at the high acid concentration could be attributed to the following factors: (I) Chromium (VI) species were more easily reduced in acidic conditions than in neutral or alkaline conditions, according to Equations (17) and (18). The molar fraction of the Cr₂O₇²⁻ was drastically increased with increasing acid concentration.

(II) The corrosion of steel slice was accelerated at high acid concentration, which made the Fe²⁺ more exposed and reacted with chromium (VI) like Equation (11). (III) the acidic conditions also promoted the conductivity of the solution, which then increased the reduction of chromium because of the increasing amount of extra free-electron (Equation (16)).

3.1.3. Effect of Reaction Temperature

During the process, reaction temperature is an important parameter affecting the reaction during the diffusion process [13]. The effect of reaction temperature on the reduction efficiency was tested, while other conditions kept constant—initial concentration of chromium (VI) of 1.000 g/L, current density of 0.05 A, and dosage of H₂SO₄ of 0.50 mL. The results showed in Figure 3 indicated that the reduction of chromium (VI) could be easily achieved at higher reaction temperature. High temperature would decrease the diffusion resistance and favor the contact of Fe²⁺ and chromium (VI), resulting in high reduction efficiency.

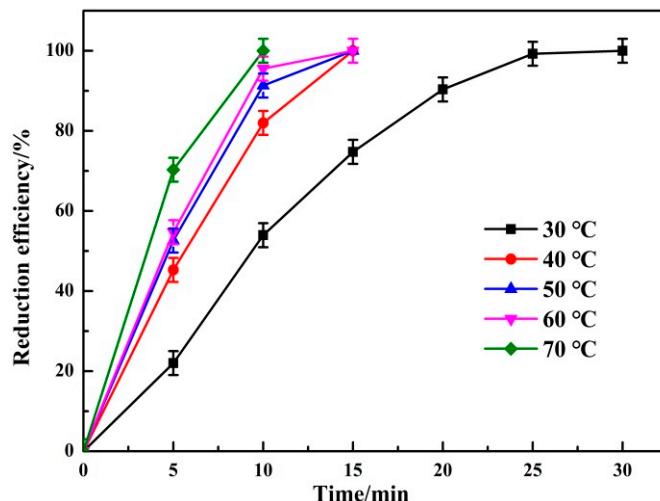

Figure 3. Effect of reaction temperature on reduction efficiency of chromium. (Volume of H_2SO_4 = 0.50 mL, initial concentration of Cr (VI) = 1.000 g/L, Current intensity = 0.05 A).

3.1.4. Effect of Current Intensity

The results showed in Figure 4 summarized the effect of current intensity on the reduction efficiency. It could be concluded that the current intensity had no obvious effect on the reduction efficiency, as the reduction efficiency increased little as current increased from 0.01 A to 0.05 A.

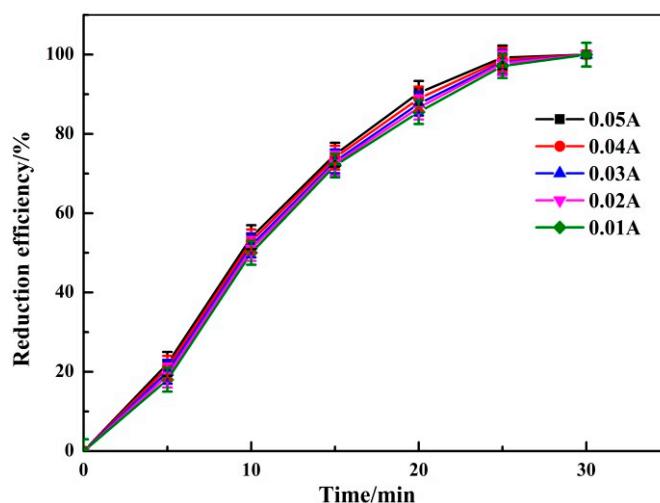

Figure 4. Effect of current intensity on reduction efficiency of chromium. (Volume of H_2SO_4 = 0.50 mL, initial concentration of Cr (VI) = 1.000 g/L).

3.2. Response Surface Methodology

3.2.1. Experimental Design

The single factor experiment was time intensive and ignored the effects of the interactions between different factors. Response surface methodology was used to observe both the effect of the independent variables on the response as well as their possible interactions [29–31]. In this study, the Design-Expert software was used to design the experiments. Central composite design (CCD) was applied to investigate the effects of parameters on the reduction efficiency of chromium. The operation parameters included: A: dosage of H_2SO_4 , B: current intensity, C: reaction time, and D: reaction temperature. The actual values for each parameter are detailed in Table 1.

Table 1. Levels for parameters in actual values.

Independent Parameter	Unit	Level		
		-1	0	1
A: H ₂ SO ₄	mL	0	0.5	1.0
B: Current Intensity	A	0.01	0.03	0.05
C: Reaction Time	min	5	17.5	30
D: Reaction Temperature	°C	30	45	60

3.2.2. Model Fitting

The natural logarithm, which was presented in terms of the coded values for the reduction efficiency after insignificant terms were excluded, and shown in Equation (19):

$$\begin{aligned} \ln(\eta) = & -5.05833 + 8.80332 \times A + 31.11897 \times B + 0.18792 \times C + 0.15777 \times D + 0.27417 \times A \times B \\ & - 2.21816E - 003 \times A \times C - 1.32521E - 003 \times A \times D + 0.054482 \times B \times C - 0.14186 \times B \times D - \\ & 1.06258E - 003 \times C \times D - 5.86586 \times A^2 - 399316804 \times B^2 - 2.37553E \times C^2 - 1.17429E - 003 \times D^2 \end{aligned} \quad (19)$$

The results of the responses for reduction efficiency in the form of analysis of variance were indicated in Table 2. The *F*-value and *p*-value for the model was 61.87 and <0.0001, respectively, which indicated the model was significant and could be used to monitor the optimization. The *p*-value of A, C, and D were all <0.0001, which indicated that A, C, and D affected the results significantly, which was consistent with the results above.

Table 2. Analysis of variance for the response.

Source	Sum of Squares	Z	Mean Square	F Value	p-Value Prob > F
Model	79.95	14	5.71	61.87	<0.0001
A	36.48	1	36.48	395.23	<0.0001
B	0.025	1	0.025	0.27	0.6080
C	9.40	1	9.40	101.82	<0.0001
D	3.31	1	3.31	35.83	<0.0001
Residual	1.38	15	0.092	-	-
Lack-of-fit	1.38	10	0.14	-	-
Pure error	0.000	5	0.000	-	-

$$R^2 = 0.9830, R_{adj}^2 = 0.9671, Pre-R^2 = 0.8803, Adequate precision = 24.594.$$

3.2.3. Response Surface Analysis

The residuals were almost located at a straight line, as shown in Figure 5, which indicated that the errors exhibited a normal distribution. The plot of the predicted versus the actual responses was summarized in Figure 6. The results showed that the predicted values were in good agreement with the experimental values, indicating that the model was valid and successfully fits the experimental data. Furthermore, Figure 7 showed that the residuals scattered randomly, which implied that the models suggested were adequate and there was no reason to suspect any violation of the independence or constant variance assumption.

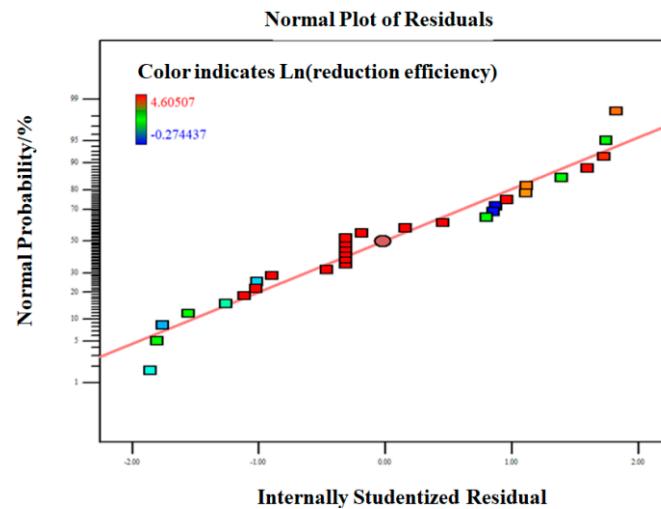

Figure 5. Normal probabilities of the residuals.

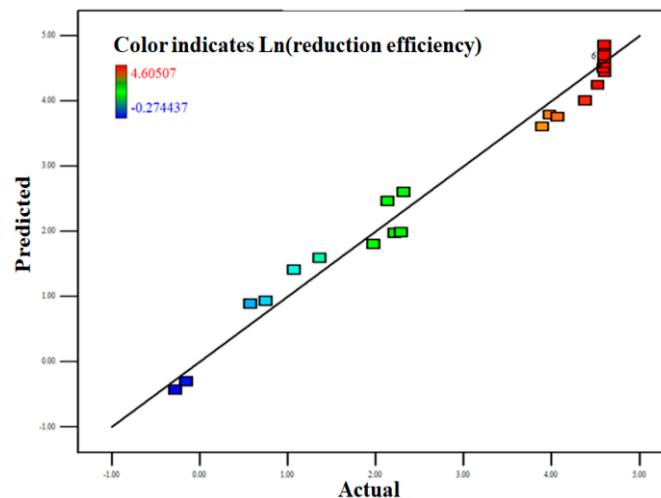

Figure 6. Plot of the predicted responses vs. the actual values.

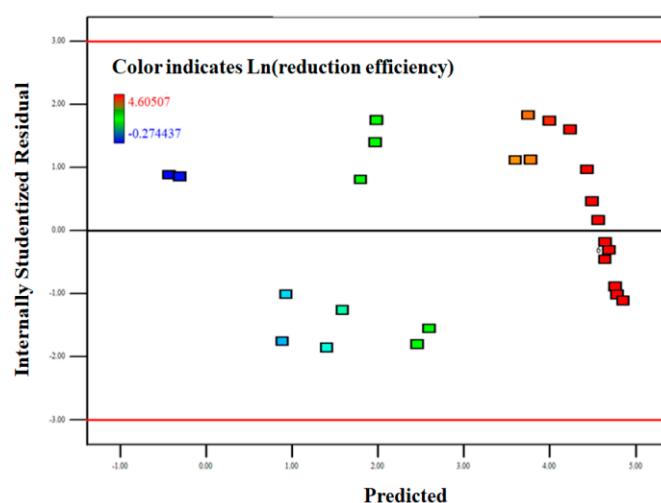

Figure 7. Plot of the residual responses vs. the predicted responses.

A perturbation plot (Figure 8) showed a comparison of all the parameters at a selected point in a chosen design space. The reduction efficiency was modeled by changing only one parameter at its range, while others held constant. The simulation results indicated that the influence of the single

parameter on the reduction efficiency followed the order: A: dosage of H_2SO_4 > C: reaction time > D: reaction temperature > B: current intensity. The comparatively sharp line of the dosage of H_2SO_4 significantly affected the reduction efficiency in the design space. That is, the coefficient of the dosage of H_2SO_4 in Equation (19) was extremely high. Equation (19) and the perturbation plot showed that the current intensity exhibited curvature effects. The reduction efficiency approximately increased linearly with increasing reaction time and reaction temperature in the chosen design space.

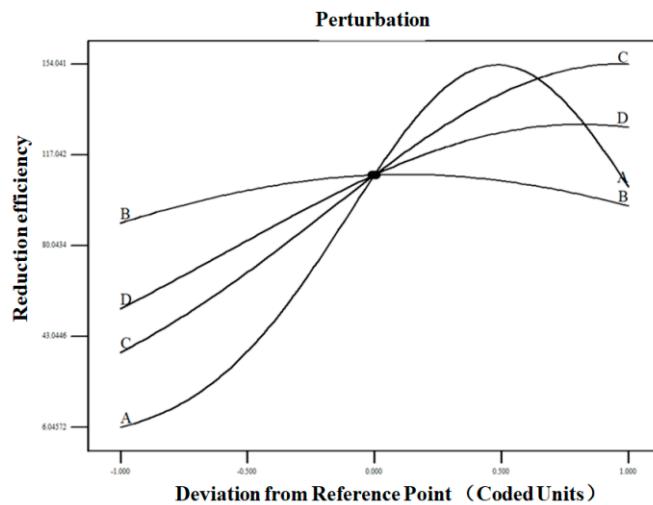

Figure 8. Perturbation plot for the reduction efficiency of vanadium in the design space: A: dosage of H_2SO_4 , B: current intensity, C: reaction time, D: reaction temperature.

The 3D Response surfaces were plotted to understand both the main and interactive effects between two affected parameters. Figure 9 summarized the interaction of each affected parameter. The results showed that the reduction efficiency of chromium first increased with the increase of dosage of H_2SO_4 , while other parameters held constant and then decreased as the volume of $\text{H}_2\text{SO}_4 > 0.8 \text{ mL}$. Also, reaction time and reaction temperature were important parameters affecting the reduction efficiency, which was consistent with the common results. The current intensity had no obvious influence on the reduction efficiency; it was only needed to apply an appropriate potential or current intensity during the process.

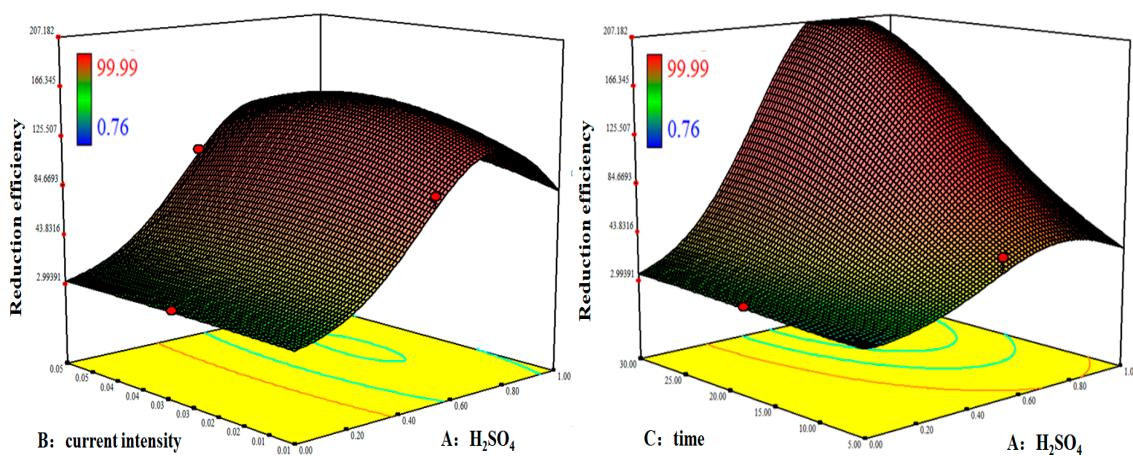

Figure 9. Cont.

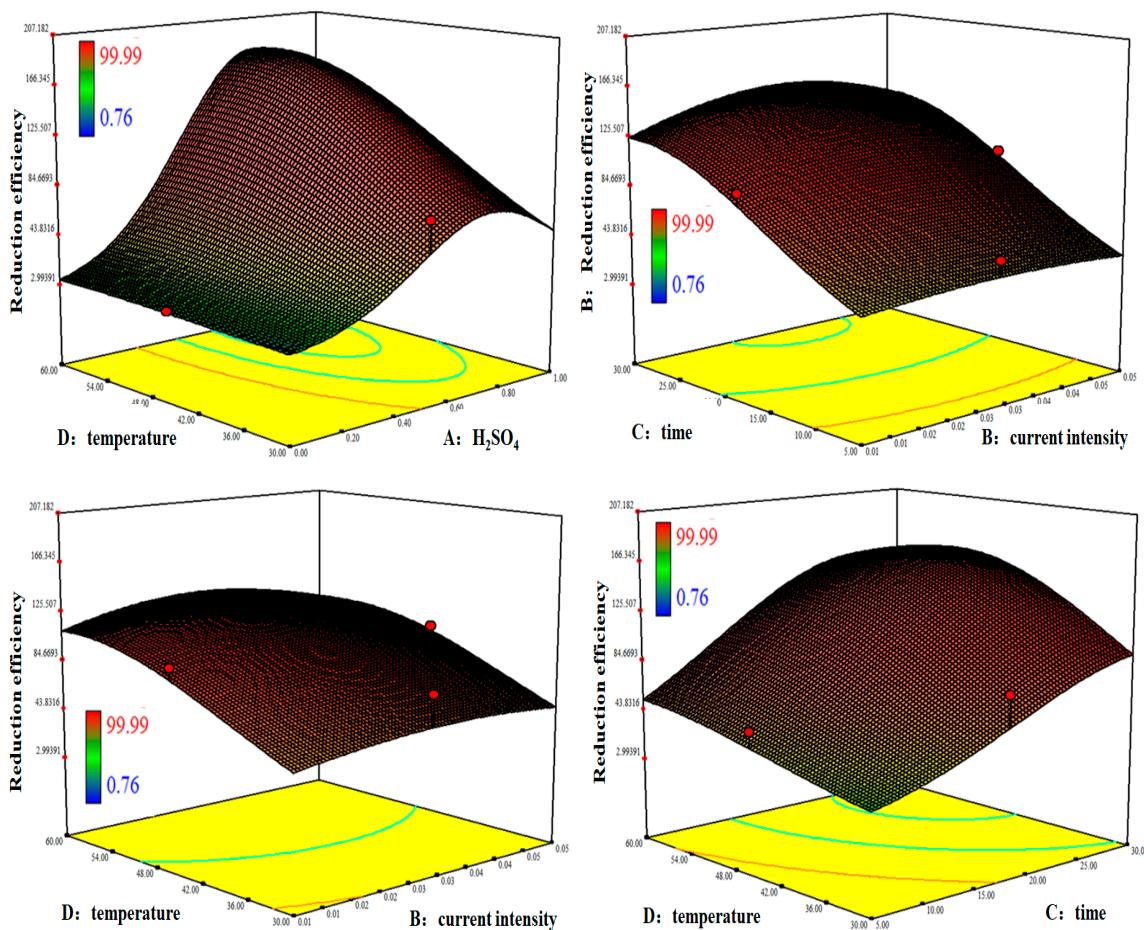

Figure 9. 3D Response surfaces of reduction efficiency.

In summary, the reduction efficiency of chromium was affected significantly by dosage of H₂SO₄ and reaction temperature, and reaction time came second, while current intensity was the last.

3.3. Removal of Chromium (III)

After reduction process, the chromium in the solution was existed as Cr (III) and it was removed by hydrolysis precipitation method [32]. Chromic hydroxide was precipitated with the addition of NaOH and filtration.

4. Conclusions

In this study, an electrocoagulation-like technology electro-reduction was applied to reduce hexavalent chromium to trivalent chromium. The main results were summarized as follows:

(1) The reduction efficiency was affected significantly by dosage of H₂SO₄. The results optimized by response surface methodology indicated that the influence of single factor on the reduction efficiency followed the order: A: dosage of H₂SO₄ > C: reaction time > D: reaction temperature > B: current intensity.

(2) The reduction efficiency was hardly affected by current intensity, while it was increased with the increasing of reaction time and acid concentration. The reducing agent, Fe²⁺ and an extra free electron, acted as the reducing agent and could easily reduce hexavalent chromium to trivalent chromium at high temperature in acid medium.
