Abstract: The present work deals with the development of a finite element methodology for obtaining the stress distributions in thick cylindrical HK40 stainless steel pipe that carries high-temperature fluids. The material properties and loading were assumed to be random variables. Thermal stresses that are generated along radial, axial, and tangential directions are generally computed using very complex analytical expressions. To circumvent such an issue, probability theory and mathematical statistics have been applied to many engineering problems, which allows determination of the safety both quantitatively and objectively based on the concepts of reliability. Monte Carlo simulation methodology is used to study the probabilistic characteristics of thermal stresses, and was implemented to estimate the probabilistic distributions of stresses against the variations arising due to material properties and load. A 2-D probabilistic finite element code was developed in MATLAB, and the deterministic solution was compared with ABAQUS solutions. The values of stresses obtained from the variation of elastic modulus were found to be low compared to the case where the load alone was varying. The probability of failure of the pipe structure was predicted against the variations in internal pressure and thermal gradient. These finite element framework developments are useful for the life estimation of piping structures in high-temperature applications and for the subsequent quantification of the uncertainties in loading and material properties.

Keywords: probabilistic finite element method; HK40 stainless steel; axisymmetric finite elements; random variables; material and load variability; Monte Carlo simulation

1. Introduction

Axisymmetric pressurized thick cylindrical pipes are widely used in chemical, petroleum, and military industries, in fluid transfer plants and power plants, as well as in nuclear power plants due to ever-increasing industrial demand. These pipes are generally introduced to excessive pressures and temperatures that are either steady or continuous. In general, it is very difficult to exactly estimate the thermal stresses generated on structural components such as thick pipe due to pressure and temperature changes. Therefore, probability theory and mathematical statistics have been applied, which allows the safety to be determined both quantitatively and objectively based on the concepts of reliability. The stress distribution in nuclear power plant piping systems remains a main concern, and deterministic structural integrity assessment needs to be combined with probabilistic approaches in order to consider uncertainties in material and load properties. The deterministic finite element method for a defined problem can be transformed to a probabilistic approach by considering some
of the inputs as random variables. The uncertainty associated with the strength prediction can be calculated by simulation techniques such as Monte Carlo simulation, which allow the values for basic stiffness variables to be generated based on their statistical distributions (i.e., probability density functions). A relevant strength variable for pipe is the elastic modulus, and load variables include internal pressure and temperature change. The objective herein was to compile statistical information and data based on literature review regarding both strength and load random variables relevant to thick pipe structure for the quantification of the probabilistic characteristics of these variables. The quantification of random variables of loads and material properties in terms of their means, standard deviations, or coefficients of variation and probability distributions can be achieved by data collection and analysis. The initial step is to gather as much data in order to consider what is appropriate for the unarranged variables under study. The second step is concerned with the statistical analysis of the data to determine the probabilistic characteristics of these variables.

Zhou and Tu [1] carried out a work to estimate the service life of a high-temperature furnace, which is very difficult due to the variability of creep data. To study the random nature of service life, a new stochastic creep damage model is proposed in their work. A comparison with results calculated using the Monte Carlo method verified the creep damage model. The randomness of the creep damage was demonstrated with a calculation on HK40 furnace tubes, providing an effective means of assessing the reliability of the furnace tubes. In the present work, the material parameters of the HK40 were adapted from Zhou and Tu [1]. SM Rehman et al. [2] investigated the natural frequencies and bulking loads for cylindrical shells with and without cracks. Chanleyew Taye and Alem Bazezew [3] studied the creep analysis of boiler tubes by finite element method. In their work, an analysis is developed for the determination of the creep deformation of an axisymmetric boiler tube subjected to axisymmetric loads.

Heat flux determination finds its application in the field of materials processing [4–6]. Holm Altenbach et al. [7] presented a creep model to reflect the basis features of creep in structures including the evaluation of inelastic deformations, relaxation and redistribution of stresses, as well as the local reduction of material strength. The solutions were compared with the finite element solutions of ANSYS and ABAQUS finite element codes with user creep model subroutines. The geometric parameters and loading conditions for the present work were adopted from Holm Altenbach [7]. Finally, Oliver C. Ibe [8] presented a study of the fundamentals of applied probability and random processes. The present work follows the probabilistic equations, and a comprehensive review on the contour method has already been carried out by Prime and DeWald [8]. Node correction in a control volume mesh is not possible because the mesh needs to be regular. That weakness is not present in the finite element based finite volume method (FEMFVM).

The stress induced by thermal gradient through the wall is given by [9]:

\[
\sigma_r^T (\text{Radial stress}) = \frac{E\alpha(\Delta T)}{2(1-\mu)\ln a} \left[ -2\ln \left( \frac{\tau_0}{r} \right) + \frac{(\tau_0)^2}{a^2-1} \ln a \right],
\]

\[
\sigma_\theta^T (\text{Circumferential stress}) = \frac{E\alpha(\Delta T)}{2(1-\mu)\ln a} \left[ 1 - \ln \left( \frac{\tau_0}{r} \right) - \frac{(\tau_0)^2}{a^2-1} \ln a \right],
\]

\[
\sigma_z^T (\text{Axial stress}) = \frac{E\alpha(\Delta T)}{2(1-\mu)\ln a} \left[ 1 - 2\ln \left( \frac{\tau_0}{r} \right) - \frac{2\ln a}{a^2-1} \right].
\]
\[
\sigma_r^T (\text{Radial stress}) = \frac{E\alpha(\Delta T)}{2(1-\mu) \ln a} \left[ -2 \ln \left( \frac{r_0}{r} \right) + \frac{(r_0)^2}{a^2-1} - 1 \right] \sigma_\theta^T = \frac{E\alpha(\Delta T)}{2(1-\mu) \ln a} \left[ -2 \ln \left( \frac{r_0}{r} \right) + \frac{(r_0)^2}{a^2-1} - 1 \right] \ln \left( \frac{r_0}{r} \right) + \frac{(r_0)^2}{a^2-1} + 1 \right) \]

(4)

\[
\sigma_r^T (\text{Axial stress}) = \frac{E\alpha(\Delta T)}{2(1-\mu) \ln a} \left[ -2 \ln \left( \frac{r_0}{r} \right) + \frac{(r_0)^2}{a^2-1} - 1 \right] \]

(5)

2. Analytical Solution

2.1. The Stresses for Thick-Walled Cylinder Pipe under Internal Pressure (P) and Thermal Gradient (\(\Delta T\))

Radial stress is given by [10]:

\[
\sigma_r = \sigma_r^P + \sigma_r^T, \quad (6)
\]

\[
\sigma_r = \frac{P}{a^2 - 1} \left[ 1 - \frac{(r_0)^2}{r^2} \right] + \frac{E\alpha(\Delta T)}{2(1-\mu) \ln a} \left[ -2 \ln \left( \frac{r_0}{r} \right) + \frac{(r_0)^2}{a^2-1} - 1 \right] \ln \left( \frac{r_0}{r} \right) + \frac{(r_0)^2}{a^2-1} + 1 \right) \]

(7)

Circumferential stress is given by:

\[
\sigma_\theta = \sigma_\theta^P + \sigma_\theta^T, \quad (9)
\]

\[
\sigma_\theta = \frac{P}{a^2 - 1} \left[ 1 + \frac{(r_0)^2}{r^2} \right] + \frac{E\alpha(\Delta T)}{2(1-\mu) \ln a} \left[ 1 - \ln \left( \frac{r_0}{r} \right) - \frac{(r_0)^2}{a^2-1} + 1 \right] \ln \left( \frac{r_0}{r} \right) + \frac{(r_0)^2}{a^2-1} + 1 \right) \]

(10)

Axial stress is given by:

\[
\sigma_z = \sigma_z^P + \sigma_z^T, \quad (11)
\]

\[
\sigma_z = \frac{P}{a^2 - 1} 2\mu + \frac{E\alpha(\Delta T)}{2(1-\mu) \ln a} \left[ 1 - 2 \ln \left( \frac{r_0}{r} \right) - \frac{2 \ln a}{a^2-1} \right] \]

(12)

Finally, von Mises stress is given by:

\[
\sigma_v = \frac{1}{\sqrt{2}} \sqrt{\left( \sigma_r - \sigma_\theta \right)^2 + \left( \sigma_\theta - \sigma_z \right)^2 + \left( \sigma_z - \sigma_r \right)^2}, \quad (13)
\]

where \(\sigma_\theta^P\) is the hoop stress induced by pressure (MPa); \(\sigma_r^P\) is the axial stress induced by pressure (MPa); \(\sigma_r^T\) is the radial stress induced by pressure (MPa); \(P\) is the pressure in (MPa); \(r_0\) is the outer radius (mm); and \(r_i\) is the inner radius (mm); \(a\) is the ratio of outer to inner radius:

\[
a = \frac{r_o}{r_i} \quad (14)
\]

\(r\) is the radius at any position of the tube wall (mm); and \(\mu\) is Poisson’s ratio. \(\sigma_\theta^T\) is the hoop stress induced by thermal stress (MPa); \(\sigma_z^T\) is the axial stress induced by thermal stress (MPa); \(\sigma_r^T\) is the
radial stress induced by thermal stress (MPa); \( E \) is the elastic modulus of the material (MPa); \( \alpha \) is the thermal expansion coefficient of the material (1/°C); \( \Delta T \) is the thermal gradient of the outer wall, and the inner wall temperature is:

\[
\Delta T = T_i - T_0.
\]  

A thick-walled cylinder pipe carrying high-temperature liquid is considered. The fluid inside the pipe was assumed to completely fill the pipe and exert a constant pressure \( P \). The analysis was carried out in the 2-D plane of the cross section of the pipe (see Figure 1).

The pipe was made up of material HK40 as per Zhou and Tu [1]. It was stressed to a pressure of 40 MPa. The temperature of the fluid flowing inside the pipe \( T_i \) was 500 °C, and the outside temperature \( T_0 \) was 420 °C (i.e., the pipe was subjected to a thermal gradient \( \Delta T \) of 80 °C [11]).

The dimensions of the thick pipe section were taken as \( L \) of 100 mm, \( r_i \) of 25 mm, and \( r_o \) of 50 mm. The material properties of HK40 are given as follows: elastic modulus \( E \) of \( 1.38 \times 10^5 \) Pa, Poisson's ratio \( \mu \) of 0.313, thermal expansion coefficient \( \alpha \) of \( 1.5 \times 10^{-5} \) (1/°C). The obtained values of the radial stress, circumferential stress, axial stress, and von Mises stress are shown in Table 1. Graphs of different stresses vs. radius are shown in Figure 2 and 3.

Table 1. Analytical results of the pipe.
3. Axisymmetric Finite Element Analysis Using ABAQUS Software

A pipe made up of HK40 material was considered with a pipe length $L$ of 100 mm, inner radius $r_i$ of 25 mm, and outer radius $r_o$ of 50 mm. The material properties are elastic modulus ($E$) of $1.38 \times 10^5$ MPa, Poisson’s ratio $\mu$ of 0.313, coefficient of thermal expansion ($\alpha$) of $1.5 \times 10^{-5}$ (1/°C). The model was meshed with element type CAX4R, a four-noded bilinear quadrilateral element, and the mesh grid was $10 \times 10$ elements and was fixed in the axial direction U2 of 0, as shown in Figure 4. The loading conditions were internal pressure $P = 40$ MPa, inside temperature $T_i$ of 500 °C, outside temperature $T_o$ of 420 °C, thermal gradient $\Delta T$ of 80 °C. Figure 4 shows the model with meshing and applied boundary conditions in ABAQUS. Analysis on the sweep of different stress elements before and after analysis is shown in Figures 5–8 below, along with comparisons of various stresses which are shown in Figures 9–11. Tables 2–3 show the comparisons of analytical and finite element analysis (FEA) using ABAQUS results by using von Mises stress.

3.2. Comparison of Analytical Results and FEA Results Using Abaqus and FEM Using MATLAB
4. Probabilistic Study

4.1. Monte Carlo Simulation

The Monte Carlo method involves randomly sampling the distributed input variables many times so as to build a statistical picture of the output quantities. This method has a wide range of applicability, with engineering applications being only one. The Monte Carlo method is particularly appropriate when there is a large number of independent variables that can influence the outcome. The Monte Carlo method is being used increasingly in structural integrity applications. The probabilistic simulation uses a Monte Carlo method with Latin hypercube sampling [12]. This is an efficient technique that permits a large number of distributed variables to be addressed. Each variable takes a finite number of values, each representing a range of values (i.e., a “bin”). All bins are of equal probability. The Latin hypercube algorithm ensures that all variable bins are sampled in the minimum number of trials (though not, of course, in all possible combinations). Moreover, because all bins are of equal probability, it follows that all trails are of equal probability, thus ensuring that all trails are of equal weight in the simulation [13].
4.2. Distributed Structural Parameters

The parameters that are required to calculate thermal stresses and which are taken as distributed in simulations are: elastic modulus, internal pressure, and temperature change. Normal distributions were used for stresses and lognormal distribution was used for material properties.

4.3. Lognormal Distribution

A random variable $X$ is considered to have a lognormal distribution if $Y = \ln(X)$ has a normal probability distribution. The density function of the lognormal distribution is given by:

$$f_X(x) = \frac{1}{x\sigma\sqrt{2\pi}} \exp\left[-\frac{1}{2} \left(\frac{\ln x - \mu}{\sigma}\right)^2\right], \quad 0 < x < \infty.$$  \hspace{1cm} (16)

The notations $X \sim LN(\mu, \sigma^2)$ provide an abbreviated description of a lognormal distribution. The notation states that $X$ is log-normally distributed with mean $\mu$ and variance $\sigma^2$.

4.4. Input Distribution

4.4.1. Due to Variability in Material Property

The lognormal distribution for the Young’s modulus of elasticity ($E$) is:

$$f_X(E; \mu, \sigma) = \frac{1}{x\sigma_x\sqrt{2\pi}} \exp\left[-\frac{1}{2} \left(\frac{\ln x - \mu_x}{\sigma_x}\right)^2\right].$$  \hspace{1cm} (17)

Lognormal distribution for $E = 1.38 \times 10^5$ Pa.

Monte Carlo simulations (MCSs) $N = 1000$ runs were carried out to estimate the stress distribution for the number of elements in the radial direction.

Coefficient of variance = 0.2 = $\frac{\sigma}{\mu} = \frac{\sigma_e}{E}$ \hspace{1cm} (18)

Mean = $(\mu_E) = \log\frac{\mu^2}{\sqrt{\sigma^2 + \mu^2}}$ \hspace{1cm} (19)

Standard deviation = $(\sigma_E) = \sqrt{\log\frac{\sigma^2}{\mu^2 + 1}}$ \hspace{1cm} (20)

The elastic modulus was lognormally distributed with standard deviation as $1.38 \times 10^5$ Pa. Figure 12 represents Young’s modulus due to the variation of the material properties.

![Figure 12. Young’s modulus due to the variation of the material properties.](image)

4.4.2. Due to Load Variability

Normal distribution
This distribution is the basis for many statistical methods. The normal density function for a random variable \( X \) is given by:

\[
f_X(x) = \frac{1}{\sigma \sqrt{2\pi}} \exp \left[ -\frac{(x - \mu)^2}{2\sigma^2} \right], \quad -\infty < x < \infty.
\]

It is common to use the notation \( X \sim N(\mu, \sigma^2) \) to provide an abbreviated description of a normal distribution. The notation states that \( X \) is normally distributed with mean \( \mu \) and variance \( \sigma^2 \).

In this study, \( P \) and \( \Delta T \) are random variables in \( r \)-radial and \( z \)-axial directions. The normal distribution is of the form:

\[
f_X(x; \mu, \sigma) = \frac{1}{\sigma \sqrt{2\pi}} \exp \left[ -\frac{(x - \mu)^2}{2\sigma^2} \right], \quad -\infty < x < \infty.
\]

Normal distribution for pressure

Mean = \( P \), variance = \( \sigma^2 \), coefficient of variance = 0.1 = \( \frac{\sigma}{\mu} = \frac{\text{pressure}}{\text{value}} \), standard deviation = \( (\sigma_X) = \sqrt{V} \),

pressure \( (P) = x \times \sigma_x + \mu \).

Pressure was normally distributed with mean and standard deviation of 40 and 4, respectively. The nominal distribution of pressure is represented in Figure 13 below.

![Figure 13. Nominal distribution of pressure.](image)

Normal distribution for thermal gradient \( \Delta T \):

Mean = \( \Delta T = T_i(x) - T_0 = \frac{\sigma}{\mu} = \frac{\sigma}{\Delta T = (T_i(x) - T_0)} \),

Standard deviation = \( (\sigma_X) = \sqrt{V} \),

Thermal gradient \( (\Delta T) = x \times \sigma_x + \mu \).

Variance = \( \sigma^2 \), coefficient of variance = 0.05, inside temperature was varying and outside temperature was kept constant, and thermal gradient was normally distributed with mean and standard deviation of 80 and 4, respectively. The nominal distribution of the thermal gradient is represented in Figure 14 below.
5. Probabilistic Finite Element Formulation

The development of a probabilistic finite element formulation for the axisymmetric pipe section was based on an available procedure for determining the finite element analysis of an axisymmetric pipe section. The axisymmetric section of the pipe used for finite element analysis was discretized into ten finite elements in the radial direction and 10 elements in the axial direction, and the geometry of the FE mesh is shown in Figure 15 below.

Figure 15. Finite element mesh for the geometry of an axisymmetric pipe section.

The constitutive equation for the axisymmetric pipe is given by:

\[
\sigma = C(\varepsilon - \varepsilon_0),
\] (26)

where \(\sigma\) is the resultant stress vector induced due to the combined effect of pressure and temperature gradient. The components of stress and strain vector are represented as:

\[
\sigma = (\sigma_r, \sigma_z, \tau_{rz})^T, \quad \varepsilon = (\varepsilon_r, \varepsilon_z, \gamma_{rz})^T,
\]

\[
\varepsilon_0 = (\alpha \Delta T(r, z) \alpha \Delta T(r, z) \alpha \Delta T(r, z) 0).
\] (27)

\(\varepsilon_0\) is the initial strain vector due to temperature change, \(\alpha\) is the coefficient of linear expansion, and the superscript “\(T\)” is the transpose operator. \(C\) is the constitutive matrix which is a function of \(E\), the Young’s modulus of elasticity of the isotropic material, and \(\mu\) is Poisson’s ratio. \(E\) is considered to be a random variable, and is of the form:

\[
E = E(x) = \text{LN}(\mu, \sigma^2).
\] (28)

Therefore, the material matrix can be expressed as:
\[ C(r, z) = \frac{E(r, z)}{(1 - 2\theta)(1 + \theta)} \begin{pmatrix} 1 - \theta & \theta & \theta & 0 \\ \theta & 1 - \theta & \theta & 0 \\ \theta & \theta & 1 - \theta & 0 \\ 0 & 0 & 0 & \frac{1 - 2\theta}{2} \end{pmatrix}. \] (29)

6. Derivation of Stiffness Matrix

In the next process, the four-noded finite element quadrilateral element for axisymmetric probabilistic finite element analysis with two degrees per node is denoted by \( \delta[u, w] \), where \( u(r, z) \) is the vector of radial displacement and \( w(r, z) \) is the vector of axial displacement. Since it is the axisymmetric case, displacement in the \( \theta \) direction is zero. The internal strain energy, \( U \), can be written as:

\[ U = \frac{1}{2} \delta^T \delta_e. \] (30)

where \( \delta_e \) is the element displacement vector and \( K_e \) is the element stiffness matrix of the pipe section, expressed as:

\[ K_e(r, z) = \int_{r_1}^{r_2} \int_{z_1}^{z_2} [BC(r, z)B^T]2\pi r \, dr \, dz. \] (31)

\( B \) are the strain-displacement transfer matrices (derivatives of FE shape functions) and are independent of material properties. The limits \( r_1 \) and \( r_2 \) are the inner and outer radii of the cylindrical pipe, and \( L \) is the length of pipe from \( z_1 \) to \( z_2 \). \( C \) is considered to be a random variable. The element load matrix is given by:

\[ F_e(r, z) = \int_{r_1}^{r_2} \int_{z_1}^{z_2} [BC(r, z)E]\] (32)

A Gauss quadrature integration scheme is used to evaluate the above integrals. The global stiffness matrix \( K \) is obtained by assembling all the element stiffness matrices \( K_e \). Subsequently, the nodal displacements are estimated by solving the finite element governing equation.

The global load vector \( F \) and the displacement vector obtained from this governing equation are used for calculating the strains of each element at the centroid location.

\[ [K(\omega)] [\delta(\omega)] = F(\omega), \] (33)

where \( \omega \) is a random variable. So, Monte Carlo simulations were used to simulate the stresses for each element. Finally, the stress contours for each element in the radial direction were obtained.

6.1. Material Specifications

The pipe was made up of material HK40. It was stressed to a pressure \( P \) of 40 MPa and subjected to a thermal gradient \( \Delta T \) of 80 °C. The dimensions of the thick pipe section were \( L \) of 100 mm, \( r \) of 25 mm, and \( t_o \) of 50 mm, respectively. The material properties of HK40 are given as follows: elastic modulus \( E \) of \( 1.38 \times 10^5 \) Pa, Poisson’s ratio \( \mu \) of 0.313, thermal expansion coefficient \( \alpha \) of \( 1.5 \times 10^{-5} \) (1/°C). For the numerical calculations, the random variable for Young’s modulus of elasticity is \( E \).

7. Probabilistic Study: Output Distribution

The output distribution is a complete and systematic framework for the probabilistic modeling of expected material variability and load fluctuations for the fatigue design.

7.1. Output Distribution Due to Material Variability
In order to characterize the material variability on the cyclic stress–strain and strain–life responses of the various elements under multi-axial fatigue, the various random variables were calculated. A comparison of various stresses is shown in Figures 16–19.

**Figure 16.** Comparison of radial stress and circumferential stress for different elements where $E$ is a random variable.
Figure 17. Comparison of axial stress and von Mises stress for different elements when $E$ is a random variable.

7.2. Output Distribution Due to Both Material and Load Variability
Figure 18. Comparison of radial stress and axial stress for different elements when $E, P,$ and $\Delta T$ are random variables.

Figure 19. Comparison of circumferential stress and von Mises stress for different elements when $E, P,$ and $\Delta T$ are random variables.

8. Probability of Failure of Von Mises Stress with Respect to Yield Strength

The difference in the von Mises stress lies in the selection of the shell face being either positive or negative, commonly known as SPOS and SNEG in ABAQUS [14].

Probability of failure:

$$P_F = P[\sigma_V > S_Y] = 1 - P[\sigma_V \leq S_Y].$$ (34)

Yield strength ($\sigma_Y$) = 241 MPa for HK40 (austenitic heat-resistant stainless steel) material. Probability in the failure of von Mises stress is represented in Figure 20 below.
9. Stress Contours

The contour method was used to measure the stress in the component normal to the section surface for both left and right sides, as shown in Figures 21–24. Generally, in the contour method, we can study the numerical data in order to verify that it could accurately measure various types of stresses. In our study, we measured various stresses (i.e., radial, circumferential, axial, von Mises) of the HK40 material.

9.1. Mean Stress Contours for HK40 Material
Figure 21. (a) Mean and (b) standard deviation of radial stress.
Figure 22. (a) Mean and (b) standard deviation of circumferential stress.
Figure 23. (a) Mean and (b) standard deviation of axial stress.
10. Conclusion

The results were stated and proved with the help of ABAQUS software and FEM using MATLAB, and a very good match was obtained among all of these findings. The finite element framework was enhanced to find the effects of uncertainties in pipe structure due to material properties and loading. Random variable models were used to model the variabilities in material properties and load by using Monte Carlo simulations. Monte Carlo simulations were used to study the probabilistic characteristics of the stress distribution of the pipe structure. The values of thermal stresses obtained from the variation in material properties (e.g., modulus of elasticity) were found to be low compared to the case where the load alone was varying.

The present methodology was used to estimate the probabilistic distributions of thermal stresses against the variations arising due to material properties as well as variations due to thermal loading. The probability of failure of the pipe structure was predicted against the variations in internal pressure and thermal gradient, and finally the results in the contour method indicated that it could be very similar to the results obtained using the analytical formula, when an asymmetrical cut was made, by averaging the stress components of both sides of the cut. The developed methodology could be helpful for the life assessment of piping structures used for high-temperature practices against creep and fatigue failures in further studies.

Nomenclature

\( \sigma_r^T \) Radial stress
\( \Delta T \) Thermal gradient
\( \sigma_z^T \) Axial stress
\( \sigma_\theta^T \) Circumferential stress
\( \sigma_\theta^p \) Hoop stress induced by pressure
\( \sigma_z^p \) Axial stress induced by pressure
\( \sigma_r^p \) Radial stress induced by pressure
\( r_0 \) Outer radius (mm)
\( r_i \) Inner radius (mm)
\( a \) Ratio of outer to inner radius
\( \mu \) Poisson’s ratio
\( r \) Radius at any position of tube wall (mm)
\( E \) Elastic modulus of material (MPa)
\( \alpha \) Thermal expansion coefficient of material

**Author Contributions:** S.A., S.B. contributed to the overall conceptualization, development of a finite element methodology for obtaining the stress distributions in thick cylindrical HK40 stainless steel pipe. S.A. contributed to the overall conceptualization, architecture and the design evaluation. S.M.R. contributed to the 2-D probabilistic finite element code developed in MATLAB. S.A. contributed to the estimation of the probabilistic distributions of thermal stresses against the variations arising due to material properties as well as variations due to thermal loading. S.B. contributed to the conceptualization and implementation of the agreement services. S.B. contributed to the editing and other final services to finish the analysis.

**Funding:** This research received no external funding.
